most important and interesting herpetological events of recent years." The discovery is primarily due to Mr F A Sampson, who, in July last year, found the adult animal as well as a larva in the Rock House Cave, Missouri, and forwarded both to the U S National Museum Mr George E Harris afterwards went to great trouble in order to procure additional specimens. Unfortunately, he has only succeeded so far in obtaining larvæ, but Mr. Stejneger hopes to be able to secure more adults. A more detailed anatomical description of this interesting animal is postponed until then, as he has not felt justified in mutilating the type specimen beyond what was necessary in order to ascertain the character of the vertebræ. The present preliminary description is, therefore, only prepared in order to call attention to the discovery and to supply the diagnosis by which the animal may be identified.

DR MORRIS GIBBS contributes to *Science* an interesting paper on the food of humming-birds. He has carefully dissected many humming-birds, both old and young, but has never found anything to convince him that the birds live on insects. It may be that at times when flowers are scarce some species of insects are captured, but Dr Gibbs is satisfied that in season, when flowers are abundant, the ruby throat of Michigan lives on honey.

In a recent investigation of the action of accumulators, Herren Neumann and Streintz have shown (*Wied Ann*) that lead has the power of absorbing hydrogen. In one case the metal was used as an electrode, and charged with electrolytic hydrogen, in another it was melted, and a current of hydrogen passed through it. Care must be taken that the charged metal is not in contact with air, as the oxygen of the latter then unites with the hydrogen, and this, the authors think, is why previous observers have not been able to prove an occlusion of hydrogen by the lead plates of accumulators. The authors examined other metals, and they give the following numbers for the gas absorbed per unit volume of metal—Lead, 0.15, palladium, 502.35, spongy platinum, 29.95, platinum black, 49.30, gold, 46.32, silver, 0.00, copper, 4.81, aluminium, 2.72, iron, 19.17, nickel, 16.85, cobalt, 153.00. When the same pieces of metal were repeatedly used, the occluding power generally fell off, in the case of the noble metals this is thought to be due to increased density, but why the occluding power of iron and cobalt should be reduced to one-half or more was not explained. Nickel and copper retained their power. With regard to the high power of cobalt, the authors tried that metal in a voltmeter, but curiously it showed no hydrogen polarization when the charging circuit was opened.

MESSRS. WILLIAMS AND NORGATE'S Natural Science Catalogue (No. 9) includes classified lists of books and periodicals on mathematics, astronomy, meteorology, physics, electricity, chemistry, microscopy, optics, mechanics, engineering, technology, &c., in French, German, and other foreign languages.

THE opening meeting of the one hundred and thirty-ninth session of the Society of Arts was held yesterday (Wednesday) evening. The following arrangements have been made for the ordinary meetings—November 23, "The Disposal of the Dead," by F. Seymour Haden, November 30, "The Copper Resources of the United States," by James Douglas, December 7, "The Chicago Exhibition, 1893," by James Dredge, December 14, "The Utilization of Niagara," by Prof. George Forbes, F.R.S. The following papers, for which dates have not yet been fixed, will be read—"Transatlantic Steamships," by Prof. Francis Elgar, "The Detection and Estimation of Small Proportions of Inflammable Gas or Vapour in the Air," by Prof. Frank Clowen, "The Purification of the Air Supply to Public Buildings and Dwellings," by William Kay, "Pottery Glazes: their Classification and Decorative Value in Ceramic Design,"

by Wilton P Rix, "The Chemical Technology of Oil Boiling, with a Description of a New Process for the Preparation of Drying Oils, and an Oil Varnish," by Prof. W Noel Hartley, F.R.S., "The Mining Industries of South Africa," by Bennett H. Brough, "Ten Years of Progress in India," by Sir William Wilson Hunter, "Australasia as a Field for Anglo-Indian Colonization," by Sir Edward N C Braddon, Agent-General for Tasmania, "Indian Manufactures," by Sir Juland Danvers, late Public Works Secretary, India Office, "Caste and Occupation at the last Census of India," by Jervoise Athelstane Baines, Imperial Census Commissioner for India, "Mexico, Past and Present," by Edward J Howell, "Newfoundland," by Cecil Fane, "New Zealand," by W B Percival, Agent-General for New Zealand. The following courses of Cantor lectures will be delivered on Monday evenings, at eight o'clock. Prof Vivian Lewes, "The Generation of Light from Coal Gas" (four lectures, November 21, 28, December 5, 12), Dr J A Fleming, "The Practical Measurement of Alternating Electric Currents" (four lectures, January 30, February 6, 13, 20), Prof W Chandler Roberts-Austen, F.R.S., "Alloys" (three lectures, March 6, 13, 20), Lewis Foreman Day, "Some Masters of Ornament" (four lectures, April 10, 17, 24, May 1), C Harrison Townsend, "The History and Practice of Mosaics" (two lectures, May 8, 15). A special course of six lectures, under the Howard bequest, will be delivered on the following Friday evenings at eight o'clock. Prof W C Unwin, F.R.S., "The Development and Transmission of Power from Central Stations" (January 13, 20, 27, February 3, 10, 17).

THE additions to the Zoological Society's Gardens during the past week include a Squirrel Monkey (*Chrysothrix sciurea*) from Guiana, presented by Mrs K Belts, a Brown Capuchin (*Cebus fatuellus* ♀) from Brazil, presented by Miss L. Blackburn, a Himalayan Bear (*Ursus tibetanus* ♀) from Burmah, presented by Major W H Cunliffe, a Herring Gull (*Larus argentatus*) British, presented by the Rev Sidney Vatcher, a Goshawk (*Astur palumbarius*) captured at sea, presented by Capt F Manley, an Egyptian Vulture (*Neophron percnopterus*) from Africa, presented by Mr J L Teage, two — Buntings (—) from North Africa, presented by Lord Lilford, F.Z.S., eighteen Filfolia Lizards (*Lacerta muralis* var *filfolensis*) from the Island of Filfolia, eighteen Wall Lizards (*Lacerta muralis* var *tiliguerta*), an Ocellated Sand Skink (*Scopeloglossus*), a Moorish Gecko (*Tarentola mauritanica*), a Turkish Gecko (*Hemidactylus turcicus*) from Malta, presented by Capt Robert A Threshie, a Common Kite (*Milvus ichnus*) from Spain, received in exchange, five Dingos (*Canis dingo*), born in the Gardens.

## OUR ASTRONOMICAL COLUMN.

THE NEW COMET—The weather has prevented observations of the new Comet. Its brightness is about that of the nebula in Andromeda, and it has been suggested that it is a return of Biela's Comet.

COMET BROOKS (AUGUST 28)—The following is a continuation of the ephemeris of Comet Brooks for the present week, extracted from *Astronomische Nachrichten*, No. 312—

124 Berlin M.T.										
1892.	R A app.	h.	m.	s.	Decl app.	"	"	Log r.	Log Δ	Br
Nov. 17	10 25 3				-2 35 2					
18	29 40	..			3 34 7					
19	34 20	..			4 34 8					
20	39 3	..			5 35 3		0.0674	9.9568	20.51	
21	43 48	..			6 36 2					
22	48 36	..			7 37 5					
23	53 27	..			8 39 0					
24	58 20	..			9 40 8	..	0.0540	9.9483	22.70	

The unit of brightness occurred on August 31

The motion of this comet will be noticed from the above ephemeris to be very rapid in a southerly direction, amounting to about  $1^{\circ}$  per day

**THE LIGHT OF PLANETS**—The question as to whether the light of planets is capable of casting shadows must have, especially during the last few months, been in the minds of many, and perhaps many observations have already been made, but unfortunately not published. With regard to this question, *L'Astronomie* for November contains two notes, the first of which, communicated by M. Marcel Moye on August 30, relates to the planet Mars. His observations were made just before the meridian passage and in a room where the light of the planet could enter the open window. In this way white paper invisible in the corners of the room was easily distinguished when placed on the wall opposite the window, while one could see well the shadows between the fingers of the hand, placing a newspaper in the light of Mars only the place of the table and the number of the words could be recognized, but not read, as was the case with Jupiter. M. Moye concludes then that Mars certainly casts shadows, less strong than those of Jupiter but still appreciable.

In the note on the light of Venus M. Leon Guiot tells us that on August 29, when about to get up to observe Jupiter, he was astonished at the brilliancy of the light that entered his window. Observing his watch, which was hanging on the wall, he was actually able to trace its shadow on the wall, for he says that all was visible as in the light of the moon, one could even read the newspaper. It was about this time that Venus was constantly seen with the naked eye in full daylight.

**STELLAR MAGNITUDES IN RELATION TO THE MILKY WAY**—Prof. Kapteyn is the author of an important memoir, which is published in the *Bulletin du Comité International Permanent pour l'exécution photographique de la carte du ciel*, relative to an observed systematic difference between the photographic and visual magnitudes of stars depending on their distance from the Milky Way. Prof. Kapteyn first noticed that a difference existed in 1890, but in the present paper he presents a preliminary account of the results he has obtained. The clichés which have been under examination were exclusively those made at the Cape Observatory for the chart mentioned above. In this discussion he has adopted the two following laws: (1) that increasing the time of exposure in the proportion of 1 to 2.5, the fraction of a magnitude gained is 0.7, and (2) the atmospheric extinction of actinic rays rises to  $2\frac{1}{2}$  above the visual rays. Since there is an undoubted difference between the photographic and visual magnitudes, denoting this difference by the symbol  $\Delta m$ , the author commences to investigate whether this quantity is ever equal to zero, that is when the photographic and visual magnitudes are equal, and if so to find the locus of these points. Charting the points down on a map and connecting them up by means of curves, the latter are found to follow in a striking manner the path of the Milky Way. Table II gives the values of  $\Delta m$  obtained from several clichés, and the positive values lie without exception between these two curves, while the negative ones are situated without. Taking into consideration both bright and faint stars, that is stars from the 4th to the 10th magnitude, the author finds that there is a strong relation depending on their galactic latitude exists between them, whether they be even very near or distant from the Milky Way, and the same systematic variation of  $\Delta m$  apparently holds good, being represented by the formula

$$\Delta m = a + \kappa \beta$$

representing the galactic latitude and  $\kappa = -0^m.0099 \pm$

$$0^m.0010.$$

In seeking for an explanation of the difference, Prof. Kapteyn investigates each possible cause singly. His conclusion, to state briefly, amounts to this, that, if one considers the stellar magnitudes given in the "Uranometrie" and in Gould's "Catalogue of Zones" (it is from these two sources that he has obtained the visual magnitudes) to be correct and not subject to systematic errors amounting sometimes to as much as half a magnitude, then it must be concluded that the light of the stars situated in the Milky Way or in its vicinity is much richer in actinic rays than those at considerable galactic latitudes. We may remark that the publication of this paper has been purposely

hurried owing to the importance of the matter therein, but although sufficient observations have not been taken in account for a very rigid investigation, Prof. Kapteyn hopes to eliminate many of the difficulties and accidental errors by the discussion of clichés of different regions of the sky, differing in galactic latitudes, made at equal altitudes, on similar plates, with equal lengths of exposure.

**THE CANALS OF MARS**—The late opposition of Mars, and the re-observation of the doubling of the canals has brought forward many theories relative to this very curious phenomenon. There seems to be no doubt now that this doubling is not due to instrumental deficiencies, or even to an optical delusion caused by the fatigue of the eyes, but that it is a real observed fact and therefore requires a rigid explanation. Omitting the now well known hypotheses suggested up till quite lately, the most recent is that put forward by M. Norman Lockyer and which is recorded in *NATURE*, vol. xlii p. 448. Mr. Lebour also (*NATURE*, vol. xlii p. 611) points out the likeness of these markings to the cracks produced in glass broken by torsion, adding that the chief characteristic features in the Mars' lines are there produced. In *Comptes rendus* (No. 18) for October 31 M. Stanislas Meunier relates another possible cause, and illustrates the phenomenon experimentally. The experiment is as follows—He takes a polished metallic surface and on it traces a series of lines and spots, representing as nearly as possible the Martian surface as seen by us, and illuminates it all by sunlight. He then stretches at some distance (a few millimetres) from it a fine transparent piece of muslin. Looking at the surface through this medium he finds that all the lines and spots are doubled, and, "se germent par suite de l'apparition, à côté de chacune d'elles de son ombre, dessinée sur la museline par la lumière que le métal a réfléchi." A fact observed by M. Schiaparelli is that the canals when doubled are not always exactly parallel, and that sometimes there is an "aspect de nébulosité." These and other peculiarities are, according to M. Meunier, reproduced by simply undulating the muslin. His explanation is that the solar light is reflected from the planet's surface very unequally, that from the continents exceeding that emitted by the deeper parts, seas and canals. Although the atmosphere is a limpid one, we are unable to see its motions, but if, as he says, the aerial envelope includes a transparent veil of fog at a suitable height, a contrast would be produced, as was the case with the muslin, by the production of shadows "qui pour un œil placé ailleurs que sur le prolongement des rayons réfléchis, à côté de chacune des surfaces peu réfléchissantes, une image pareille à elle." This explanation of the phenomena of shades by reflection if valid should of course hold good for the planet Venus when properly situated, and that it is not observed on the Moon is only another proof that our satellite has no atmosphere.

## GEOGRAPHICAL NOTES

*THE Revue Française* states that a subterranean town, laid out with regular streets in a series of great caverns, near Karki, on the right bank of the Amu daria, has recently been explored. Pottery and metal work were found amongst the ruins, and from the coins and inscriptions seen the town must have been occupied at least as early as the second century B.C.

By the new constitution of the United States of Brazil the seat of government is to be transferred from Rio de Janeiro to a site upon the central plateau where an area is to be marked off as a federal district. A scientific mission under Senor Cruls has been appointed to examine the region where the three rivers, São Francisco, Tocantins, and Parana, take their rise at an elevation of over 3,000 feet, with the view of finding a suitable site for the new capital.

Mr. D. J. RANKIN communicates to the *Scottish Geographical Magazine* an account of his journey up the Zambesi in 1890-91, with a map of the country between the Zambesi and Shire. He found the Zambesi freely navigable for light-draught steamers as far as the Acababassa Falls, more than 300 miles from the sea, the Lupala narrows presenting no difficulty. Between Lupala and Acababassa extensive coal deposits occur, and these are sure to become valuable. Beyond the falls after a portage of about thirty miles, the Zambesi is again navigable

to Zumbo, and thence for a distance of 300 miles up the Loangwe river

A NOMINATION to the geographical studentship of £100 in the University of Oxford will be made at the end of Hilary term, 1893. Particulars of the appointment may be obtained from Mr. Mackinder, the Reader in Geography.

Two sudden deaths of men known in connection with minor exploration and geographical writing are announced. Mr. Theodore Child, author of "South American Republics" and other works, died of cholera at Ispahan, and Lieutenant Frederick Schwatka, who has travelled extensively in Alaska, committed suicide in Portland, Oregon.

MR. PRATT, whose departure for the head waters of the Amazon was announced in this column at the time, has been compelled to relinquish the expedition on account of ill-health, and is now in this country.

AT the first meeting of the Royal Geographical Society the certificates of 106 new members, including 15 ladies, were read. This is the largest number seeking admission into the society which has yet been proposed at one time.

### DR NANSEN'S ARCTIC EXPEDITION

DR. FRIDTJOF NANSEN opened the session of the Royal Geographical Society on Monday night by a description of his plans for crossing the north polar region, and received a most enthusiastic reception from a crowded audience. His scheme involves two separate considerations: (1) the direction of the prevailing polar currents, and (2) the means by which these currents can be utilized for transporting an expedition. All attempts to reach the pole by Smith Sound, by the east coast of Greenland, and by the north of Spitzbergen have been complicated by contrary currents, the few expeditions by way of Bering Sea, although equally unsuccessful, have had the currents in their favour.

Taking into account all the available data, it appears that the polar current between Greenland and Spitzbergen carries southward between 80 and 120 cubic miles of water every twenty-four hours. The Gulf Stream drift may carry 60 or 70 cubic miles of water a day into the polar basin north of Nova Zembla, about 10 or 14 cubic miles daily; probably flow in through Bering Strait, and possibly about one cubic mile a day of fresh water pours in on the average from the great Siberian rivers. This comparatively small addition of fresh water must account for the salinity of the Greenland outflowing current being somewhat less than the average salinity of the North Atlantic. Theoretically there would thus appear to be a current running from near the New Siberian Islands towards the north of Greenland.

The existence of such a current is strongly indicated by the drift of the *Jeannette* from  $71^{\circ} 30'$  to  $77^{\circ} 15'$  N. after being caught in the ice, this drift being northwestward from Bering Strait. Again, articles lost on the sinking of the *Jeannette* in the latter position off the New Siberian Islands were found on an ice-floe near Julianhaab, in the south of Greenland. A throwing stick, of a kind made only by the Eskimo of Alaska, was found a few years ago near Godthaab, on the west of Greenland. Siberian driftwood is stranded regularly on the coasts of Greenland, and even on the north coast of Spitzbergen. These facts can only be accounted for by the theory of an ocean current across the polar basin. The evidence of the relative thickness of ice in different parts of the Arctic Sea, and of the occurrence of Siberian diatoms in the mud of ice floes between Greenland and Iceland is strongly confirmatory.

Dr. Nansen intends to make the northwesterly current transport him across the middle of the polar basin, and to give him an opportunity for making scientific observations nearer the pole than has ever previously been done. He will sail next June via the Kara Sea for the New Siberian Islands, thence work a way as far north as possible, when stopped, he will run into the ice, and await the time when he will be drifted into the open sea again between Greenland and Spitzbergen. He has had a ship built in Norway expressly for the voyage. Her form is such as to cause the ice, on closing round, to lift her out of the water, and she will rest upright on its surface. This vessel, named the *Fram* (i.e. Forward), is built of very long-seasoned timber, and is more strongly put together than any other vessel of her size. The same timbers are of great thickness, and set close together,

so that if all the planking were stripped off the vessel would remain water tight. The planking is first a ceiling of pitch pine, alternately 4 and 8 inches thick, then outside two layers of oak, 3 and 4 inches thick respectively, and over all is an "ice sheathing" of from 3 to 6 inches of the hard and slippery greenheart. The sides are thus from 28 to 32 inches thick of solid wood. The decks are equally strong, and the cabins are planned so as to be isolated by store rooms and coal-bunkers from the sides, while non-conducting materials such as cork, felt, and reindeer hair are introduced between the walls or decks and the rooms to guard the crew from cold.

The vessel is sharp fore and aft, and both propeller and rudder may be lifted in wells so as to avoid risk of fouling the ice. The rudder is deeply immersed when in action, so that floating ice will not touch it. Both stem and stern overhang greatly, and are heavily plated with iron to crush and cut through thin ice. The length of keel is 101 feet, and the length of deck over all is 128, while the greatest beam (exclusive of ice sheathing) is 36 feet, and the depth 17 feet. These proportions are very unusual, but were adopted as the result of experience in other ships. With light cargo she will draw 12 feet, and fully loaded 15½, the displacement being about 800 tons. She is rigged as a three-masted schooner, with square sails on the foremast, and has an engine of 160 indicated horse-power. The crow's nest on the mainmast is 105 feet above the water line, so as to give a wide horizon for the look out. Two large decked boats are carried, in either of which the whole crew of twelve men could live if the ship were lost. Dogs, sledges, ski, several small boats, canvas for building extra boats on an emergency, and provisions for five or six years are taken. A pendulum apparatus is included in the scientific outfit, which is otherwise very complete. The ship is fitted with electric light; the dynamo may be worked by a windmill when coal can no longer be spared, or as a last resort it can be driven by a capstan arrangement adapted for four men, thus supplying healthy exercise and useful work to one third of the crew, and abundant light to the remaining two-thirds.

The duration of the voyage cannot be estimated, as it will entirely depend on the rate of drifting, which must vary considerably from year to year, but judging from the movement of the *Jeannette* relics, two years ought to suffice.

### A REMARKABLE CASE OF GEOMETRICAL ISOMERISM

AN exceptionally interesting memoir is contributed to the current number of *Liedig's Annalen* by Prof. Wulicenus of Leipzig, who has latterly identified himself so earnestly with the subject of molecular configuration. It has been suspected for some years that there are two isomeric unsaturated acids of the composition  $C_8H_7COOH$ . One of these substances exists in the free state in the roots of *Angelica archangelica* and has therefore received the name of *angelic acid*. The other compound is found along with angelic acid in Roman oil of cummin and has been termed *tiglic acid*. These two acids, moreover, behave so similarly in almost all their reactions with other substances that the conclusion has been rendered inevitable that they must be represented not only by the above formula, but by

the same constitutional formula,  $CH_3CH \begin{matrix} \diagup CH_3 \\ \diagdown COOH \end{matrix}$  That

the two acids are not identical, however, was indicated by certain slight differences of behaviour, and Prof. Wulicenus felt convinced that the two were in fact geometrical or stereoisomers, the difference consisting in a different arrangement of their various radicle groups in space. He considers it probable that the nature of the difference may be represented in one plane by the following formulæ.

Judging from previous experience of the behaviour of other geometrical isomers of a similar nature, it appeared probable that the halogen addition products of the two acids would exhibit differences so marked as to determine definitively the separate nature of the two acids. Under the direction of Prof. Wulicenus, therefore, one of his pupils, Herr Pückert, undertook the investi-

gation of the bromine addition products of angelic and tiglic acids, and was successful in showing that the two products were essentially different, exhibiting properties indeed so dissimilar that their identity was entirely out of the question. Although their similar constitution was indicated by melting-points differing by only one or two degrees, yet it was found that the crystals of the dibromide of angelic acid immediately reacted with water with production of a colourless oil, whilst the dibromide of tiglic acid remained unchanged in contact with water, moreover, the two compounds upon decomposition of their sodium salts, yielded two mono brom-pseudo-butylenes, which differed essentially in their capability of reacting with alcoholic potash.

In the year 1890, however, Prof Fittig, of Strassburg, who had previously investigated the subject in conjunction with Herr Pagenstecher, and had obtained *identical* bromine addition products from the two acids, published a paper in the *Annalen* in which he sought to show that the results of Herr Puckert were incorrect, and that the two substances were identical. Prof Fittig has since requested Prof Wislicenus to withdraw the work or substantiate it, and further charges Prof Wislicenus with seeing facts through the veil of his theory. Unfortunately Prof Wislicenus has been unable hitherto to meet the attack owing to domestic loss and serious illness, but at last he is able to publish the results of a really classical piece of work which he has carried through himself, and which not only demonstrates the truth of Herr Puckert's conclusions, but places the results beyond all criticism, and shows the singular cause of Prof Fittig's inability to repeat them. It is indeed remarkable, but nevertheless true, that the fate of the theory of geometrical isomerism has actually been trembling in the balance owing to the different situation of the draught cupboards in the Leipzig and Strassburg laboratories. In the former laboratory they are placed *between* the windows, and in deep shadow, in the Strassburg laboratory they are *against* the windows, and are consequently brightly illuminated in daylight. Now Prof Wislicenus shows that the dibromide of angelic acid is only formed in the absence of bright light, *rays of daylight intensity being absolutely fatal to its formation*. Hence Prof. Fittig only obtained the relatively more stable dibromide of tiglic acid, which in a good light is yielded by both angelic and tiglic acids. As the case is so remarkable, it may perhaps not be uninteresting to give a brief summary of the work of Prof Wislicenus.

During the course of other researches concerning geometrical isomers, it was found that in order to obtain addition-products in which no internal re-arrangement of atoms had occurred, it was necessary to observe three conditions. One must operate at the lowest possible temperature, exclude light as much as possible, and take care that the halogen to be added is always present in tolerably large excess. When these three conditions are observed, the two respective and distinct bromine addition-products of angelic and tiglic acids are always obtained. They are probably represented by the formulae:—

The operation of preparation is best conducted as follows.—A quantity of bromine, at least half as much again as is required by theory, and dissolved in three times its weight of carbon bisulphide, is placed in a flask surrounded by iced water. The flask is fitted with a triply bored caoutchouc stopper, through one hole of which is inserted a thermometer, through a second an exit tube furnished with a calcium chloride drying tube, and through the third the end of a burette containing a solution of pure angelic or tiglic acid in five times its weight of carbon bisulphide. The draught cupboard is darkened as much as possible and then the acid solution is slowly allowed to run into the flask. After the expiration of a few hours the formation of the brominated compound is complete, and the carbon bisulphide may be evaporated away in a rapid stream of dry air.

The difference between the two compounds is apparent even at this early stage, for the tiglic compound commences to crystallize long before the removal of all the carbon bisulphide, and soon forms a snow-white mass of crystals. On the contrary,

the angelic dibromide shows no sign of crystallization, remaining as an oil for some time after the removal of all the carbon bisulphide. Eventually it crystallizes to a hard yellowish mass. The only solvent from which it was found practicable to re-crystallize the angelic dibromide was the pentane fraction of petroleum ether boiling at 33–39°.

The melting-point of pure angelic dibromide is 86.5–87°. That of tiglic dibromide is 87.5–88°. The two substances behave quite differently upon resolidification. The former congeals to a transparent resinous mass, whilst the latter forms an opaque solid.

The most striking difference is apparent in their respective behaviour towards water. The dibromide of tiglic acid is only slightly soluble in water, and dissolves unchanged, crystallizing out again upon evaporation. The dibromide of angelic acid, however, instantly combines with the equivalent of one molecule of water, to form a curious unstable liquid, an oil of high refractive power, which is somewhat soluble in excess of water, and is again deposited upon evaporation. This liquid compound is also formed when the dibromide is exposed to moist air, while the dibromide of tiglic acid is not changed in a moist atmosphere. In dry air the angelic liquid compound again dissociates into the dibromide and water vapour. In fact the dibromide of angelic acid would appear to act as an excellent indicator of the hygroscopic state of the atmosphere.

The two dibromides show a further difference in solubility, the angelic compound being far more readily soluble in all the solvents experimented with.

Finally the crystals of the two compounds, although both belonging to the triclinic system, are absolutely unlike. From measurements made by Dr. Fock, they are shown to exhibit different forms, entirely different angles, and different disposition of optic axes.

From the above description it will be quite evident that the two compounds are certainly not identical.

In conclusion, Prof Wislicenus gives the results of attempts to obtain the dibromide of angelic acid in bright sunshine in the open air, then when working in front of a window, and again when the experiment was performed upon a table in the centre of the laboratory. In the first case, instead of the angelic compound, 92.8 per cent of the dibromide of tiglic acid was obtained, in the second case 89.6, and in the third case 88.7 per cent. These results render it perfectly clear why Prof. Fittig could not obtain the angelic compound in his experiments, and they also show how it is possible for two chemists, both working with a desire to ascertain the truth, occasionally to obtain results apparently at complete variance with each other.

A. E. TUTTON

## MARINE LABORATORIES IN THE UNITED STATES<sup>1</sup>

ONLY in comparatively recent times has the tremendous importance of the bearing of the invertebrates upon the general questions of biology been appreciated. We have seen that some work was done upon these animals at an early date, when the minds of workers were not much troubled by theoretical considerations, but the study of the adult forms is a small part of a real understanding of these animals that it was unsatisfactory work, and never became popular among investigators until embryological methods had been introduced.

Dr. Brooks has remarked that "nearly every one of the great generalizations of morphology is based upon the study of marine animals, and most of the problems which are now awaiting a solution must be answered in the same way." We find the reason for this in the fact that the biology of the present day is a study of vital phenomena and of natural laws governing living things. The importance of the invertebrates depends, therefore, upon the fact that in them life exists under simplified conditions, affording opportunities for the study of questions for which higher forms are, with our present knowledge, too complex.

As the study of invertebrates has extended, it has become more and more desirable to have more favourable conditions for this work, more abundant facilities for collecting and oppor-

<sup>1</sup> Reprinted from "Biological Teaching in the Colleges of the United States," by John P. Campbell, Professor of Biology in the University of Georgia, issued by the U. S. Bureau of Education.  
<sup>2</sup> Johns Hopkins University Circulars, vol. vi., p. 37.

unities for studying animals alive. Much of the early work was done upon specimens collected and stored in museums, but workers, both in this country and Europe, had frequently made excursions to the seacoast for the purpose of studying the invertebrate forms constituting so large a part of the marine fauna.

The unsatisfactory nature of this work was of course evident. Suitable accommodations and working appliances could not be provided under these circumstances, and desirableness of establishing permanent seaside laboratories was early felt. Nothing was done, however, in this country until 1871, when John Anderson, a wealthy citizen of New York, presented to Prof. Agassiz the island of Penikese in Buzzard's Bay, together with the sum of \$50,000 with which to found a seaside station for the study of marine life. Another friend gave him a yacht of 80 tons burden for use in collecting. Agassiz had long wished for such a laboratory, and no one but himself could have aroused the necessary enthusiasm for carrying out the project. He soon set to work and built large laboratories, with suitable accommodations for a large number of workers. In 1873 they were opened for work. This constituted the first opportunity enjoyed by American students of studying marine animals in their native waters, with proper appliances for work. It inaugurated a new era in scientific research, being the first outward expression of an idea which has since taken a firm hold upon the investigators of the country. The death of Agassiz in December, 1873, put an end to the project. The buildings were used but two seasons and then abandoned.

Of this laboratory Prof. Whitman says —

"At the close of the second and last season at Penikese, in 1874, Alexander Agassiz appealed to the colleges and all interested boards of education for support, but all in vain, for not a single favourable reply was received, and so his intention to remove the laboratory to Wood's Holl was never carried out. Thus that great and memorable undertaking, after absorbing money enough to build and equip a most magnificent laboratory, was abandoned from lack of interest on the part of educational institutions rather than of means. Such a failure, it must be frankly confessed, is not one to inspire confidence, but its explanation removes the apparent grounds for discouragement. It was the marvellous personality of Prof. Agassiz that made Penikese a possibility. It was his magic influence that created that school, his commanding individuality that organized and vitalized it. All interests centred in him so completely that with his sudden removal the enterprise was left without a soul. The school had no coherency except in his magnetic power and intellectual strength, and the moment these elements of stability were withdrawn, collapse followed as a natural and inevitable consequence. Then, too, it should be remembered that Prof. Agassiz lived just long enough to demonstrate the impracticability of maintaining such a school in such a locality, but unfortunately not long enough to convince the scientific world of its utility. The school was an experiment, its master was stricken down before it could be fairly tested, and the times were not ripe for it."

The establishment of this laboratory was an event of the greatest significance because of its bearings upon the history of education. Not only was Penikese the first biological station established in this country, and, indeed, in the world, but it was the beginning of the summer-school movement which has spread so generally over the country, and which, it should be noted, began with original research and finally extended to include the work of elementary instruction.

The movement met with the cordial support of naturalists everywhere, and was almost immediately followed by the establishment of Dohrn's magnificent station at Naples. Soon after, in 1875, a seaside station was established at Helder by the Netherlands Zoological Society, and other smaller ventures followed in Europe.

The need of opportunities for seaside study in the United States was too generally felt by those who had come under Agassiz's influence for the project to be allowed to stop. The advantages of this method of work over museum study had impressed themselves at least upon a few workers, and accordingly we find several attempts made to found new laboratories. They differed in character and aims, but all agreed in being founded upon the one idea of studying marine animals in their native waters.

The most direct successor of the Penikese laboratory is the

private laboratory of Prof. Alexander Agassiz at Newport. While this building is constructed on a much smaller scale than that at Penikese and is open only to a limited number of workers, yet it is prominent for the elegance of its appointments and its conveniences for work.

The first laboratory for seaside study established in this country after the abandonment of Penikese was maintained by the Peabody Academy of Sciences, under the guidance of Prof. Packard, with the co-operation of Prof. Kingsley and others. This laboratory was for elementary instruction rather than research, and remained in existence only from 1876 to 1881.

In 1878 the trustees of the Johns Hopkins University made an appropriation to allow a party of workers to spend some time in seaside study. The party was under the guidance of Dr. W. K. Brooks, who had himself been a pupil of Agassiz and a member of the Penikese laboratory. The location selected was at the lower part of the Chesapeake Bay, from which the name of Chesapeake Zoological Laboratory was chosen. No permanent buildings were erected, as it was intended, if possible, to change the location from year to year, but an outfit of boats and collecting apparatus was provided. The summers of 1878 and 1879 were spent about the lower part of Chesapeake Bay at Crisfield, Md., and Fort Wool, Va., at which places special attention was given to the development of the oyster.

At the opening of the third season, in 1880, the need was felt of a locality that would offer a greater variety of objects for study, and accordingly the summers of 1880-82 were spent at Beaufort, N. C. This locality proved especially favourable, since sand bars, mud flats, salt marshes, and land-locked salt water, within easy reach, gave a large variety of different rare forms, and there was also abundant ocean dredging. A sufficient appropriation was made in 1880 to purchase a steam launch and a sloop, which put the workers in a position to take every advantage of their opportunities.

In 1883 a special study of oyster beds made a return to the mouth of the Chesapeake Bay necessary, and that season was spent at Hampton, Va., but the following two seasons were again spent at Beaufort.

In 1886 the need of a more southern location was felt, and the Bahama Islands seemed to offer an inviting field. The summer of 1886 was therefore spent at Green Turtle Cay, and the following summer at Nassau, New Providence.

Financial difficulties temporarily stopped the work of the laboratory, but it is announced that it will be reopened in the summer of 1891.

It is difficult to summarize the work of this laboratory, and none the less so to over estimate its importance. It enjoys the distinction of being the first marine laboratory ever carried successfully into operation in the United States, and its work was entirely original research. The character of work done differed from year to year, according to the facilities which the different localities offered, but in general it may be said that embryology received most attention, while considerably less was devoted to the discovery and description of new species. The methods employed, as well as the new facilities enjoyed, made it possible to apply effective means of solution to many problems previously obscure, as well as opening many questions in regard to which nothing had been done.

Of the lasting value of the work it is perhaps too early to speak, but the fact that over one hundred papers, based upon work there performed, have readily found publication in the best journals of this country and Europe, as well as the fact that much of the work has already found its way into standard textbooks, gives strong testimony to its value.

The Chesapeake Zoological Laboratory may be regarded as the successor of the Penikese laboratory to the extent that its aims are the same, but it differed in not being generally open to the workers of the country. Arrangements were not made for large numbers, and those who were present were mainly students of the Johns Hopkins University. During the nine years that this laboratory remained in existence, there were in all fifty investigators present, and the average length of each season was nearly two months.

The need was felt, especially in that portion of the country where Agassiz's influence was more directly exerted, of establishing a laboratory on a larger scale, and open to a larger

\* Shortly after the above was written, Kingston, Jamaica, was chosen as a suitable locality, and a party of advanced workers, numbering about fourteen in all, were present from May until September—September 27, 1891.

number of workers, and the first step taken in this direction was the founding of a laboratory by the Boston Society of Natural History. In their report for 1881 these words occur:

"It has been considered desirable to found a summer laboratory sufficient to supply the needs of a class of persons who have begun to work practically under our direction, but have hitherto had no convenient means for pursuing their studies on the seashore. We are sure that such a laboratory is

needed for a limited number of persons, such as our own pupils in natural history, and some of the teachers of the Boston public schools, about a dozen in all, but we are not sure of any real demand outside of these."

Arrangements for laboratory work were speedily made at Annisquam, Mass. Boats and appliances for collecting were at once provided, and in the spring of 1881 a circular was issued announcing the opening of the new laboratory. From this the following extracts are taken—

"The liberality and co-operation of the Woman's Educational Association enable the Boston Society of Natural History to announce that a seaside laboratory, under the direction of the curator (Prof. Alpheus Hyatt), and capable of accommodating a limited number of students, will be open at Annisquam, Mass., from June 5 to September 15.

"The purpose of this laboratory is to afford opportunities for the study and observation of the development, anatomy, and habits of common types of marine animals, under suitable direction and advice. There will, therefore, be no attempt during the coming summer to give any stated course of instruction or lectures.

"It is believed that such a laboratory will meet the wants of a number of students, teachers, and others who have already made a beginning in the study of natural history."

Twenty-two persons were attracted to the Annisquam laboratory during its first season. Prof. Hyatt, in his report for 1882, remarks as follows—

"The great need of an institution for teaching field work cannot be properly estimated by the number of those who are attracted by the opening of such opportunities for study. The mental condition of those who attend, and what it has done for them, and the sphere of influence which it reaches through them, are the only true standards by which its present and future usefulness can be properly measured. Nearly all the pupils were persons who could be termed 'well educated,' nevertheless they were, with the exception of some who had already worked in the laboratory or field, entirely unable to obtain knowledge with their own eyes and hands, and had even acquired a notion that this was not possible for anybody except the trained man of science. Several of these teachers, after their work was finished, expressed their gratefulness for the new powers the course had developed in themselves, and the fascinating pleasure they had experienced in learning to use their own eyes and hands in the study of things hitherto unapproachable for their uncultivated senses except through the deceptive mediation of books. When it is remembered that these teachers influence and mould the minds of thousands of young persons it is at the same time proved that what this laboratory has done and can do is not to be estimated by the number of its own pupils."

The success of the undertaking seemed assured, and arrangements were made for its continuance during the five years following. The number of students fluctuated greatly, falling to ten in the third year, and running up in the sixth year to twenty-six.

During these six years the laboratory was carried on jointly by the Boston Society of Natural History and the Woman's Educational Association of Boston. It has been the policy of both of these associations to originate new enterprises, but to turn them over when well started into other hands. It seemed in 1887 that the time had come when the maintenance of the laboratory should be put on a firmer basis. It had been supported long enough to demonstrate its practicability and usefulness. The demands upon it had increased. It was no longer an experiment. The associations believed that a permanent organization should be effected, the working facilities increased, and the whole established on a larger scale. Moreover, it seemed that something more might be done to give the laboratory a wider sphere of usefulness in advancing knowledge of marine life. Great as was its work in teaching, it seemed to depend for its support upon a circle of people too small for the extent of its benefits. It seemed desirable that a change should come which would lead to a more widespread interest in

the laboratory, and bring together more investigators. The Marine Biological Laboratory was the result of this movement.

While space will permit but a brief account of this laboratory, its history, development, aims, &c., it may be said that the one point which distinguished it from the Annisquam laboratory was the prominence given to research. Students are received, but from the outset there has been a settled determination to so adjust the claims of each as to secure the greatest amount of efficiency and do most to advance science. The organization was therefore effected so as to secure a permanent staff of investigators, who would always be present, increasing knowledge by their own work, and by their example stimulating others to follow. Moreover, the principle was thoroughly recognized that the best investigation is prompted by the work of teaching. The best investigator is often the best teacher, but the work of teaching reacts upon the work of investigation, influencing it for the better.

The experience of the laboratory shows that these points, which had previously been carefully considered, were well taken. Various means were resorted to for providing funds, and in March, 1888, the laboratory was incorporated.

Wood's Holl was chosen as a locality because of its convenience, accessibility, and the variety of its land and marine flora and fauna. The building was at once begun, and finished in time for work during the summer. Circulars could not be issued until after most of the colleges had disbanded for the summer, and yet during the first season seven investigators and eight students were attracted to the laboratory.

In subsequent years the growth has been a steady one. The number of workers has greatly increased, and even now, when only its third season has been passed, it is stated that the space is insufficient to meet the demands upon it, the facilities for collecting are too small, and the staff of instructors is not large enough for their classes. Its usefulness is now established, and the time is ripe for it. To it in great measure the United States must look for the advancement of biology. Let us hope that its trustees, all of whom are working biologists, may be successful in placing the laboratory upon such a financial basis that its full possibilities for usefulness may be realized.

### UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Dr. Hill, Master of Downing College, has been appointed Chairman of the Natural Science Tripos Examiners for 1893. An election to an Isaac Newton Studentship in Astronomy, Astronomical Physics, and Physical Optics, will be held in the Lent term 1893. Candidates must be B.A.'s, and under twenty-five years of age on January 1. The emoluments are £200 per annum for three years. Applications are to be addressed to the Vice-Chancellor between January 17 and 27, with testimonials or other evidence of competency.

Dr. Lorrain Smith, M.D. Edin., Demonstrator of Physiology at Oxford, and Dr. F. F. Weshbrook, M.D., Manitoba, Professor of Pathology at Winnipeg, have been elected John Lucas Walker Students in Pathology. The Managers express their high approval of the valuable researches conducted by the late student, Dr. A. A. Kanthack, of St. John's College. The State Medicine Syndicate state that, at the two examinations held in April and October, 1892, there were in all sixty-four candidates, of whom thirty-five received Diplomas in Public Health. The fee in future will be five guineas for each of the two parts of the examination in State Medicine.

Examinations for open scholarships and exhibitions in Natural Science will be held in twelve of the Colleges in December and January next. A list giving the conditions and value of the scholarships is published in the *University Reporter* of November 12, pp. 198, 199.

### SCIENTIFIC SERIALS.

Wiedemann's *Annalen der Physik und Chemie*, No. 10.—Refraction and dispersion of light in metal prisms, by D. Shea. Thin prisms of gold, silver, nickel, and cobalt were prepared by the electrolysis of cyanide solutions by Kundt's method. Prisms of platinum were also prepared by the disintegration of platinum foil. A piece of foil 4 mm. broad and 0.02 mm. thick placed perpendicularly to a piece of plate glass at a distance of 0.5 mm. produced under the action of a current of 20 amperes a double wedge-shaped layer of oxide in half an hour.

This was easily reduced by a Bunsen flame, so as to represent a metallic prism with an angle of some 20 seconds. Only one in twenty of the prisms could be used, and only one in 200 silver or gold prisms. The source of light was a zirconium burner with a red shade transmitting light of the mean wave-length  $64 \times 10^{-7}$  cm. The index of refraction was found to vary with the incidence. For perpendicular incidence the following values were found: Au 0.26, Ag 0.35, Cu 0.48, Pt 1.99, Ni 2.01, Iron 3.02, Co 3.16. For silver the index was 0.39 at an incidence of  $10^\circ$ , 0.60 at  $30^\circ$ , 0.80 at  $50^\circ$ , 1.01 at  $80^\circ$ , and 1.03 at  $90^\circ$ . The following refractive indices for various wave-lengths illustrate the dispersion.

	$L_i, a$	D	F	G
Au	0.29	0.66	0.82	0.93
Ag	0.25	0.27	0.20	0.27
Cu	0.35	0.60	1.12	1.13
Pt	2.02	1.76	1.63	1.41

—On a law of refraction for the entrance of light into absorptive media, by H. E. J. G. du Bois and H. Rubens.—On the infra-red emission spectra of the alkalis, by Benjamin W. Snow.—Absolute change of phase in light by reflection, by Paul Glan.—Inductive representation of the theory of double refraction, by Franz Kolláček.—Studies in the electric theory of light, by D. A. Goldhammer.—On the passage of feeble currents through electrolyte cells, by Rud. Lohnstein.—On the motion of the lines of force in the electro-magnetic field, by Willy Wien.—On the electric theory of magneto-optic phenomena, by D. A. Goldhammer.—An automatic interruptor for accumulators, by H. Ebert. This is to prevent the current from the accumulator exceeding the supply for which it is constructed. Two mercury cups are inserted in the circuit, connected by a piece of stout copper wire. The current next passes through an electro-magnet. As soon as the current reaches a certain strength the electro-magnet overpowers an adjustable spring, and lifts the copper connecting-piece out of the cups.—Contribution to the history of the spheroidal phenomena, by G. Berthold.

## SOCIETIES AND ACADEMIES

### LONDON

Physical Society, October 28.—Dr J. H. Gladstone, F.R.S., past president, in the chair.—The discussion on Mr Williams's paper, "On the relation of the Dimensions of Physical Quantities to Directions in Space," was opened by Prof. Perry reading a communication from Prof. Fitzgerald, president. The writer said Mr Williams disagreed with the suggestion that electric and magnetic inductive capacity are quantities of the same kind principally because he had not got over the curious prejudice that potential and kinetic energy are different. No theory of the ether could be complete unless it reduced its energy to the kinetic form. Electric and magnetic inductive capacity would probably be found to be similar in the ether, and ultimately have the same dimensions. The analogies were not yet complete, but only in respect of *matter* was it probable that any difference existed between them. Diamagnetism corresponded to electrostatic induction, but paramagnetism had no definite electrical analogue. He was inclined to regard the phenomena of paramagnetism as connected with the arrangement of the material molecules, whilst diamagnetism depended on the electric charges on those molecules. So far no matter had been found which conducts magnetism, and such may not exist in our universe, but it may be gravitationally repelled by matter as we know it.—Mr Madan remarked that in the first part of his paper Mr Williams recognized that dimensional formulæ were originally change-ratios, but puts this aside for the higher conception which regards the formulæ as expressing the nature of the quantity. Fourier showed how to find the dimensions of units by making the size of the fundamental units vary. But  $k$  (specific inductive capacity) did not vary with the fundamental units, for it was merely the ratio of the capacities of two condensers, and therefore, by Mr Williams's definition, a pure number. It was difficult, he said, to see how  $k$  could have dimensions, but Mr Williams regarded it as a physical quantity, and therefore possessing dimensions. The object in giving dimensions to  $k$  and  $\mu$  seemed to be to get over the double system of units. Mr Madan did not think that dimensions could express the nature of physical quantities, and said differences of opinion existed amongst authorities on this point. For example, Dr J. Hopkinson, at the last B.A. meeting, said that because a co-efficient of self-induction had the dimensions of

length it must be a length, whilst other learned professors objected to this view. Even if one admitted that dimensions are a test of the nature of physical quantities, it was not necessary that the two systems of units should be identical. The connecting link between the two systems was  $Q = C t$ , and the validity of this equation had been questioned. If this objection be confirmed, then there would be no current in electrostatics and no  $Q$  in the electromagnetic system, and the units would not clash. Referring to dynamical units, Mr Madan pointed out that two units of mass were used in astronomy, but astronomers got over the difficulty by using a co-efficient. Dimensional formulæ, he said, are the result of a convention that certain definitions should hold true generally, but they contain no further information respecting the nature of the quantities beyond that involved in those definitions. As an example of the inability of such formulæ to express the nature of quantities, he pointed out that whilst physical differences were known to exist between + and - electricity the dimensional formulæ showed no signs of such differences.—Prof. Rucker said every correct physical equation consisted of a numerical relation between physical quantities of the same kind, and might be written either as a mere numerical equation or as a relation between the physical quantities themselves. The equation  $2 + 1 = 3$  may correspond to 2 feet + 1 foot = 3 feet, and the latter may be written  $2[L] + 1[L] = 3[L]$  where  $[L]$  represents the unit of length. So far as he was aware, nobody but a recent writer in the *Electrician* had denied that in such an equation  $[L]$  represented a concrete quantity. Maxwell explicitly stated that it does in his article on "Dimensions" ("Encycl. Brit.") and elsewhere, and Prof. J. Thomson, in his paper on the same subject, makes no statement contrary to this. The above equation might also be written  $2[\text{feet}] + 1[\text{foot}] = 3[\text{yard}]$ . Another equation involving time is  $60[\text{sec}] = 1[\text{minute}]$ , and dividing one by the other one gets

$$\frac{60}{\text{sec}} \left[ \frac{\text{foot}}{\text{sec}} \right] + \frac{1}{\text{sec}} \left[ \frac{\text{foot}}{\text{sec}} \right] = 1 \left[ \frac{\text{yard}}{\text{min}} \right]$$

A difficulty was felt here in understanding what dividing a foot by a second meant, but this difficulty Prof. Rucker considered was not greater than that involved in dividing an impossible by a real quantity, a very familiar analytical device. Reasons for regarding the symbol  $\left[ \frac{\text{foot}}{\text{sec}} \right]$  as legitimate were then given.

Prof. Henrici said the communication under discussion was one of the most important contributions to physical science which he had come across for a long time. Such difficulties as presented themselves in the paper arose from its fundamental character. The author had attempted to express all physical quantities in terms of three, but quantities may exist which cannot be completely represented in terms of  $L$ ,  $M$  and  $T$ . The tendency of modern mathematics was to express everything dynamically. Mathematicians had to go back in the habit of using quantities which were neither numbers nor concretes in the ordinary sense, and different kinds of algebra with units not understandable had been developed. If a quantity,  $a$  times a unit  $u$ , be multiplied by  $b$  times another unit  $v$ , the result is expressed by  $ab uv$ , where  $ab$  is a number and  $uv$  a new unit which may or may not be physically interpretable. The interpretation of a product depended on the meaning attached to "multiplication," and if this be restricted to "repeated addition" the range is very limited. The narrow conceptions concerning multiplication acquired at school could only be removed by a careful study of vectors. Mr Williams had treated his subject by vector methods, but a few traces of quaternions remained which might be omitted. To truly understand the subject, vectors must be treated vectorially. Dimensions might then show the nature of the quantities involved. The system adopted in Mr Williams's paper was probably the best attainable at present, but he (Prof. Henrici) looked forward to the use of a more fundamental quantity than the vector—viz. "the point"—as the ultimate basis. Grassmann had worked out a "point calculus" in 1844, which was republished in 1880. Quantities more complex than vectors, viz. rotors, screws, moirés, &c., had been used with advantage by Clifford, Ball, and others. Dr Sumpter thought the first ideas of students on the subject of dimensions were that they represented the nature of the quantities, but could not see why every quantity should be expressed in terms of  $L$ ,  $M$  and  $T$ . Prof. Rucker's paper on "Suppressed Dimensions" had cleared up several important points, and he (Dr. Sumpter) now considered that every quantity

must be expressed in terms of a unit of the same kind as itself. He viewed Mr. Williams's attempt to express everything in terms of  $L$ ,  $M$  and  $T$ , as rather a retrograde step. The discussion on Mr. Williams's paper was adjourned, and Dr. Young made some remarks on Mr. Sutherland's communication "On the Laws of Molecular Force." Mr. Sutherland, he said, thought that Ramsay and Young's law  $\partial p / \partial l = f(v)$  is not correct for compounds in the liquid state. Barus, however, had proved that several liquids, including ether, only showed variations from the law at extremely high pressures. After writing the equation of the virial in the form  $p v = RTvf(v) + v\phi(v)$ , where  $v\phi(v)$  stands for the internal virial term, the author of the paper had shown that  $v^2\phi(v)$  ought to be constant, but, finding it not constant in the case of ether, &c., he attempted to explain the discrepancies by the formation of pairs of molecules at small volumes. Other substances, such as nitrogen and methane, were supposed to follow the law. This, Dr. Young said, could not be accepted as proved, for the range of volumes over which the experiments had been made was only small, and methane was difficult to prepare pure. After criticizing the use of two and sometimes three "characteristic equations" for the same substance, he went on to show that the formulæ given in the paper by which the critical temperatures, pressures and volumes might be calculated, lead to results differing from experimental numbers by quantities greatly in excess of experimental errors. Experiment also showed that capillarity had little or no effect on the determination of critical constants. Speaking of critical volumes he pointed out that MM. Cailletet and Mathias had published a method of finding critical densities which gave very accurate results. Mr. Sutherland's conclusions respecting Van der Waals's generalizations were practically identical with those expressed by Dr. Young in his paper on the subject, read before the Society last year. The views as to the nature of the various kinds of "pairing" mentioned in Mr. Sutherland's paper were open to serious objections, for his "physical pairing" is supposed to produce more effect on the "characteristic equation" than true chemical pairing. In his (Dr. Young's) opinion the idea of physical pairing appears somewhat speculative and requires further elucidation. A paper on the determination of the critical density, by Dr. Young and Mr. A. L. Thomas, and two papers, on the determination of the critical volume, and on the boiling points of different liquids at equal pressures, by Dr. Young, were taken as read. The first paper gives an account of results obtained by Cailletet and Mathias's method, based on the fact that the means of the densities of a substance in the states of liquid and saturated vapour when plotted with temperature, lie on a straight line which passes through the critical point. In the paper on critical volumes the above-mentioned method is again referred to and results obtained thereby accepted in preference to those given by the author in his paper on Generalizations of Van der Waals, &c., read before the Society about a year ago. The alcohols do not strictly follow the straight-line law. Revised tables of critical volumes, densities, pressures, and temperatures are given, and it is pointed out that for many substances the ratio of the actual critical density to the theoretical density (for a perfect gas) is about 3.8. The paper on boiling-points of different liquids at equal pressures contains a comparison of the accuracies with which a formula for the relation between the boiling-points given by M. Colat (*Compt Rend*, cxiv p. 653), and one by Ramsay and Young (*Phil Mag.*, January 1886), accord with experimental results. The author concludes that the latter formula shows the best agreement, but that of M. Colat is satisfactory under certain conditions. The further discussions of Mr. Williams's and Mr. Sutherland's papers were adjourned till the next meeting.

**Mineralogical Society, October 25.**—At the Anniversary Meeting the following were elected Officers and Members of Council:—President, Prof. N. S. Maskelyne, F.R.S.; Vice-Presidents, Rev. Prof. S. Haughton and Dr. Hugo Müller, F.R.S.; Treasurer, Mr. F. W. Rudler, F.G.S.; General Secretary, L. Fletcher, F.R.S.; Foreign Secretary, Mr. T. Davies; Ordinary Members of Council, Prof. A. H. Church, F.R.S.; Prof. Grenville A. J. Cole, Mr. T. W. Danby, Dr. C. Le Neve Foster, F.R.S., the Rev. H. P. Gurney, Mr. J. Horné, Prof. J. W. Judd, F.R.S., Prof. G. D. Liveing, F.R.S., Lieut. General C. A. McMahon, Mr. H. A. Miers, Mr. F. Rutley, and Mr. J. J. H. Teall, F.R.S.—Dr. C. O. Trechmann detailed the results of the goniometrical measure-

ment of two very perfect crystals of Binnite collected by himself in the Binnenthal. The measurements, besides adding a large number of forms to those previously recorded for this species, serve to establish the tetrahedral hemisymmetry of the mineral which has been left as a very doubtful feature by previous observers, and was denied by Hesseberg.—Mr. H. A. Miers and Mr. G. T. Prior announced the results of further researches on the rare silver minerals known as Xanthoconite and Ruttingerite. According to their physical measurements and chemical analyses these two substances are identical, both having the same composition as Proustite, and crystallizing in rhombic shaped tables belonging to the mono-symmetric system. The name Xanthoconite, given by Breithaupt, has the priority; the red silver ores are now to be regarded as an isodimorphous (?) group consisting of the two sulph arsenites Proustite and Xanthoconite, and the two sulph-antimonites Pyrargyrite and Fireblende. Previous determinations of the composition of Ruttingerite and the crystalline form of Xanthoconite have been erroneous.—Mr. Fletcher gave a description of a new habit of Descloizite from the Argentine, and also an account of the new mineral Baddeleyite (native zirconia) the only fragment as yet found is part of a twinned crystal showing forms which belong to the mono-symmetric system pleochroic optically negative and biaxial with inclined dispersion specific gravity 6.025 hardness 6.5.—Mr. Allan Dick contributed further remarks on Geikielite, supplementing his paper read at the previous meeting.—Prof. Judd exhibited photographs in illustration of his previous paper on the lamellar structure of quartz crystals and the method by which it is developed.—Mr. Rutley exhibited a large series of beautiful cardboard models illustrative of the symmetry and optical characters of the crystalline systems.—Mr. Miers exhibited specimens, including the rare mineral Turnerite from the Tintagel Slate quarries which he had visited in search of that mineral.

**Zoological Society, November 1.**—Sir W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the months of June, July, August, and September, 1892, and called special attention to a young Gibbon from Hainan, South China, of a uniform black colour, belonging to the species recently described by Mr. Oldfield Thomas as *Hylobates hainanus*, presented by Mr. Julius Neumann, and to a young male Malayan Tapir (*Tapirus indicus*) from Tavoy, Burmah, presented by Col. F. M. Jenkins.—Mr. E. Hartert exhibited (on behalf of the Hon. Walter Rothschild) examples of two new Mammals from New Guinea (*Proechidna nigroaculeata* and *Acrobates pulchellus*), and a stuffed specimen of *Apteryx maxima* from Stewart Island.—A communication was read from Lord Lilford, giving an account of the breeding of a pair of Demidoff's Galagos in his possession.—Prof. Bell read a note on the occurrence of *Bupalus heuense* in Ireland.—Mr. Finn gave an account of his recent zoological excursion to Zanzibar.—Prof. Newton, F.R.S., exhibited and made remarks on a specimen of *Sylvia nisoria* lately killed in England.—Prof. F. Jeffrey Bell read a description of a remarkable new species of Echinoderm of the genus *Cidaris* from Mauritius, proposed to be called *C. curvatispinis*.—A communication was read from Sir Edward Newton, and Dr. Gadow, F.R.S., describing a collection of bones of the Dodo, and other extinct birds of Mauritius, which, having been recovered from the Mare aux Songes in that island by the exertions of Mr. Theodore Sauzier, had been by him entrusted to them for determination. The collection contained examples of the atlas, metacarpals, pre-pelvic vertebra, and complete pelvic bones of the Dodo, which had before been wanting, as well as additional remains of *Lophopsittacus*, *Aphanapteryx*, and other forms already known to have inhabited Mauritius. Besides these there were bones of other birds, the existence of which had not been suspected, and among them of the following, now described as new:—*Syrinx* (?) *sauzieri*, *Asurus alphonssi*, *Bulwerides mauritianus*, *Plotus nanus*, *Sarcidornis mauritianus* and *Anas theodori*, the whole adding materially to the knowledge of the original fauna of Mauritius.—Mr. Oldfield Thomas gave an account of a collection of Mammals from Nyassa-land, transmitted by Mr. H. H. Johnston, under whose directions they had been obtained by Mr. Alexander Whyte.—Dr. Günther, F.R.S., read a paper descriptive of a collection of reptiles and Batrachians from Nyassa-land, likewise transmitted by Mr. Johnston, and containing examples of several remarkable new species, amongst which were three new Chameleons, proposed to be called

*Chameleon isabellinus*, *Rhinophloeon platyceps*, and *R. brachyurus*—Mr R. Lydekker read a memoir on some Zeuglodon, and other Cetacean remains from the Tertiaries of the Caucasus—Mr. Martin Jacoby read the descriptions of some new genera and new species of Phytophagous Coleoptera from Madagascar

**Linnean Society, November 3**—Prof Stewart, President, in the chair—The Rev. Prof. Henslow exhibited an instrument used in Egypt for removing the end of the sycamore fig, and gave some account of the mode of cultivation—Mr A. Smith Woodward exhibited and made remarks on some supposed fossil lampreys (*Paleospondylus gunni*) from the old red sandstone of Calthness—The Rev. E. S. Marshall exhibited some hybrid willows from Central Scotland, believed to be rare or new to Britain—Mr G. N. Douglass exhibited the train of a peahen which had assumed the male plumage. The bird, which was reared at the Castle Farm, Tilquhillie, near Blanchory, N. B., was believed to be about thirty years old at the time of its death, and for some years previously had not laid any eggs. In the opinion of the exhibitor and others present the phenomenon was correlated with disease of the ovaries. Similar cases had occurred with fowls, pheasants, and black game, but not, so far as was known, with peafowl—Mr C. I. Druery exhibited some new examples of apospory in ferns, namely a specimen of *Athyrium filix femina* var. *clarissima* with pinnae showing development of prothalli by soral apospory, and a seedling *Lastrea pseudomas cristata*, showing prothalli developed aposporously over general surface of frond (pan-apospory)—Mr J. E. Harting exhibited some live specimens of the short-tailed fieldvole (*Arvicola agrestis*), and gave an account, from personal inspection of the serious damage done by this little rodent upon the sheep-pastures in the lowlands of Scotland—Mr A. B. Rendle exhibited some seedling plants of the sugar cane which had been raised in this country by Mr Veitch—The discussion on several of these exhibitions having continued until a late hour, a paper by Prof. Henslow, on a theoretical origin of endogens through an aquatic habit, was by consent adjourned to the next meeting of the Society, which will be held to-day

**Mathematical Society, November 10**—Prof. Greenhill, F.R.S., President, in the chair—This was the annual general meeting and after the election of the gentlemen whose names are given on p. 616 (NATURE, vol. xli.) to serve on the council for the session 1892-93, the new President, Mr A. B. Kempe, F.R.S., took the chair and at once called upon the retiring president to read his valedictory address. Prof. Greenhill took as his subject collaboration in mathematics—The following further communications were made. Some properties of homogeneous isobaric functions, by E. B. Elliott, F.R.S. This paper is a sequel to one which the writer communicated at the June meeting entitled a proof of the exactness of Cayley's number of seminvariants of a given type. The earlier part of the present paper supplies omissions in the preceding one and in the remainder the theorem on which Mr Elliott's argument was based is transformed, and the result examined for its own sake without reference to the particular application.—On certain general limitations affecting hyper-magic squares, by S. Roberts, F.R.S. The paper does not aim at making any addition to the known ways of constructing magic squares. Hyper-magic squares, as the writer regards them, include those called by M. E. Lucas "carrées diaboliques," and also treated by Mr A. H. Frost under the designation of "Nasik squares." The special form is of ancient origin. The second method given by Moschopolus (thirteenth century) is a general one for forming such squares and they have been discussed by various modern authors. The writer's object is to show some limitations to which they are subject when the elements are positive or negative integers. Incidentally it appears that hyper-magic squares of oddly even orders cannot be formed of series of consecutive natural numbers. There is some reason for believing that much ingenuity has been fruitlessly employed in trying to form such squares. We may here mention that a very interesting historical essay on the subject of magic squares has been published by Dr. Siegmund Günther, in his work entitled "Vermischte Untersuchungen zur Geschichte der Mathematischen Wissenschaften" (Leipzig 1876). The subject has also been brought into connection with the "Geometry of Tissues," by M. Lucas and others (see the "Principi Fundamentali della Geometria dei Tessuti," per Edoardo Lucas, Torino, 1880).—Note on the equation  $y^2 = x(x^2 - 1)$  by Prof. W. Burnside.—Note on

secondary Tucker circles by Mr J. Griffiths. The idea of this note sprang from the fact that if  $G, g$ , are two inverse points with respect to the circumcircle (ABC) whose centre is  $O$ , i.e. such that  $OG \times Og = R^2$ , then the pedal triangles DEF, def of  $G, g$ , with regard to ABC are similar. Taking  $G$  to be one of the Brocard points, then (DEF) is a Tucker circle and (def) a secondary circle—On a group of triangles inscribed in a given triangle ABC whose sides are parallel to connectors of any point P with A, B, C, by Mr. Tucker. If DEF, D'E'F', are a pair of such triangles they are readily seen to be in perspective. Their properties are considered with reference to the principal points and lines of the modern geometry of the triangle—A note on triangular numbers by Mr R. W. D. Christie

## PARIS

**Academy of Sciences, November 7**—M. de Lacaze Duthiers in the chair—Letter addressed to the President by the committee formed to celebrate the seventieth birthday of M. Pasteur—Influence of the distribution of manures in the soil upon their utilization, by M. H. Schlösing—Note on the reply of M. Berthelot to my note of October 24, by M. Th. Schlösing—Comparison of the magnetic observations of General Pezoff in Central Asia with the data of the English magnetic charts, by M. Alexis de Tillio. General Michael Pezoff, in his last exploring tour in Eastern Turkestan, made some careful determinations of magnetic declinations and inclinations. If these are compared with those published by M. Creach in the report of the *Challenger* expedition, it appears that in declination an average correction of  $+1''$  has to be applied to the latter, while the inclinations are practically identical—On the new triangulation of France, by M. L. Bassot. This work was commenced in 1870. It comprised the establishment of a continuous chain between the Spanish frontier and Dunkerque, supporting the net on three base lines, and attaching it as far as possible to each of the parallel chains of the old triangulation. Also a new determination of the co ordinates of the Panthéon, the fundamental point of the triangulation, the measurements of base lines in terms of the international metrical standard, and the calculation of the new arc of meridian. It was found that, starting from the Paris base-line, the network was verified at Perpignan, at a distance of  $6^\circ$ , to within 1 in 250,000. Where the French system meets the English, Belgian, and Italian systems, the correspondence is found practically perfect, but on the Spanish frontier there exists a difference of 1 in 65,000 at present unexplained. The arc between Dunkerque and Carcassonne, as now calculated, exceeds that of Delambre by  $447m$ , or 1 in 20,000—Essay on a general method of chemical synthesis, by M. Raoul Pictet—On the fifth satellite of Jupiter, by M. E. Roger. From the empirical formula for the distances of Jupiter's satellites

$$\log \text{hyp } a = 8 - \frac{3''}{2\pi} - 0.03 \cos \frac{m\pi}{5} + \dots$$

the probable distances of any satellites yet undiscovered can be calculated. It appears that there may be one at distance 1.97, two others at 1.61 and 1.27, or a single one at 1.425, and others beyond the outermost satellite. The distances of those already known are 2.50, 6.05, 9.62, 15.35, and 27.00—On the transformations of dynamical equations, by M. Paul Painlevé—Lenticular liquid microglobules and their conditions of equilibrium, by M. C. Maltézos. The smallest drops of a liquid jet falling upon another liquid often assume a lenticular shape, one surface of which is more curved than the other. These are called microglobules. Their diameters were measured, and their volumes and masses calculated. The production of microglobules in all the liquids in Quincke's table was experimented upon—Effects of weight on fluids at the critical point, by M. Gouy—Dilatation of iron in a magnetic field, by M. Berget. An elegant experiment to exhibit the lengthening of an iron bar on magnetization, on the principle of Newton's rings. The bar in question, provided with a cap of black glass, presses against the flat side of a plano-convex lens screwed to the same stand. The bar is surrounded by a coil, which can be excited by a battery of accumulators. Magnetization is at once indicated by the expansion of the rings. On the dissipation of the electric energy of the Hertz resonator, by M. V. Bjerknes (see *Wiedemann's Annalen*, No. 9).—On the equality of potential at the contact of two electrolytic deposits of the same metal, by M. G. Gourd de Villemonette.—On the rotating power of the diamine salts, by M. Albert Colson.—Volumetric determination of the alkaloids, by M. E. Léger.—On the fixation of free nitrogen by

plants, by MM Th Schloesing, jun., and Em Laurent — Observations on the preceding note, by M. Duclaux — Observations on the preceding communications, by M. Berthelot — On  $\gamma$ -achroglobine, a new respiratory globuline, by M. A. B. Griffiths — On the axinite of the Pyrenees, its forms and its conditions of occurrence, by M. A. Lacroix — On the subterranean river of the Tindoul de la Vaysière and the springs of Salles la-Source (Aveyron), by MM E. A. Martel and G. Gaupillat — On the comparative anatomy of the stomach in Ruminants, by M. J. A. Cordier — Remarks on some means of defence in the mollusks, by M. E. Hecht — On the evolution of the brachial apparatus of some brachiopoda, by MM P. Fischer and D. P. Ehlert — On the mechanism of solution of starch in plants, by M. A. Prunel — On the diuretic and ureopoeitic action of the alkaloids of cod liver oil on man, by M. J. Bouillot — Results obtained at the crystal works of Baccarat by the introduction of metastannic acid into putty powder, by M. L. Guérout

## BERLIN

Physiological Society, October 14.—Prof Munk, president, in the chair.—Prof Kossel gave an account of further researches on nucleic acid, a compound which, in union with albumin, composes the proteids of the cell-substance. In earlier researches he had studied the acid as derived from yeast cells and salmon-milt, and found that while the substances obtained from these two sources differed in many respects, they resembled each other in that the ratio of phosphorus to nitrogen was in both as 1 to 3, and that they both yielded nucleic-bases during their decomposition. More recent researches on the nuclein derived from the leucocytes of the thymus gland have shown that the nucleic acid it yields is more like that from milt, and resembles the product obtained from yeast even less than does the product from milt. The relationships of nucleic acid to the chromatin bodies of the histologists were minutely considered.—Prof. Gad brought forward a theory of the excitatory process in muscles, based upon the theory of Fick, but further developed and supported by experiments on tetanized muscles.

## ANIMALS' RIGHTS

*Animals' Rights* By H. S. Salt. (London Bell, 1892)

THIS little volume is divided into three main parts, the principle upon which the rights of animals are founded, the various ways in which they have been infringed, and the reforms necessary to secure their full recognition. Notwithstanding, however, the logical form in which the subject is thus set forth, the book is absolutely useless both from the ethical and the practical points of view. In the first place the author nowhere attempts to define the relative value of the lower animals as compared with the human race, and although he certainly allows that they possess less "distinctive individuality," he condemns the use of the terms by which they are commonly designated (such as dumb beast, live stock, or even animal), on account of the imputation of inferiority which is involved in them.

He seems to be totally unaware that not only is the natural affection of animals far less enduring, and their intellect immeasurably weaker, but that of morality, *i.e.* the doing of right for right's sake alone, unswayed by personal feeling or the influence of others, they have absolutely no conception whatever.

Ignoring, however, these fundamental distinctions from which the subjection of animals inevitably follows, Mr Salt at once proceeds to enunciate his theory of their rights.

This whole question, however, is thrown into absolute chaos by the fact that, for subsequent dealing with the practical aspects of his subject, the author has equipped himself with not merely one but two definitions of animals' rights, differing from each other so widely that while the one involves the unconditional prohibition to kill, eat, or use any harmless animal, the other would admit of all these things being done for good cause shown. Thus on page 9 we find that they have the right to live their own lives with a due measure of that restricted freedom of which Herbert Spencer speaks, *i.e.* the freedom to do that which they will, provided they infringe not the equal liberty of any other. Except, therefore, in the case of the beasts of prey, who no doubt would "will" to eat man if a convenient opportunity offered, the liberty to sacrifice the lives of animals for human food or indeed to employ them in any way is cut off without reserve. Turn, however, to page 28 and we find that this freedom of animals is no longer restricted merely by the equal freedom of others, but is also "subject to the limitations imposed by the permanent needs and interests of the whole community." A life of disease and a death from disease or old age and starvation are no longer secured to them, and the whole principle of the subordination of the interests of the lower race to those of the higher is conceded.

From the confusion of mind thus exhibited suggestions of practical value can scarcely be expected, nor indeed do we find them in the succeeding parts of the work. Thus we are told that "the contention that man is not morally justified in imposing any sort of subjection on

the lower animals" is one which the author "desires to keep clear of," and pronounces to be "an abstract question beyond the scope of the present enquiry," yet, as he also states "that no human being is justified in considering any animal as a meaningless automaton to be worked, tortured, or eaten for the mere object of satisfying the wants or whims of mankind," we would submit that he has not kept clear of the matter at all, as we cannot call to mind any forms of subjection which are not included in these three.

In his discussion of the treatment of domestic animals we would only draw attention to that passage wherein the degrading practice of pampering lap-dogs is rebuked as unworthy of their moral dignity! In the succeeding chapters the employment of animals in personal decoration, sport, and scientific experiment is dilated upon and condemned, and it then only remains to consider the question of the reforms which ought to be instituted.

The first remedy proposed is that of education. We are all to be taught to be humane, but seeing that this has been, for countless generations, carried into effect by almost every mother with almost every child, the suggestion can hardly be accounted novel nor need any great changes in the present condition of affairs be expected from it. Further, there must be a crusade preached against the disregard of the kinship of animals to ourselves, and the laugh must be turned from the so-called sentimentalists (*i.e.* those agreeing with the author's views) against certain flesh eaters, sportsmen, and scientific experimentalists whom he seems to have in his mind's eye, and who, seeing that he represents them as advancing absolutely foolish reasons for practices which they could easily defend on common-sense grounds, are very properly described by him as "cranks."

The second reform is to be found in legislation, and it might naturally be supposed that this should first be applied in that case which Mr Salt considers to be productive of the greatest bulk of suffering, namely in that of flesh eating. But this is not so, he has already said that it is no part of his present purpose to advocate vegetarianism, and he discreetly leaves it to look after itself. Then after suggesting that the worrying of tame animals might be classed as baiting, and that improvements (though what and how he does not say) might be made in the transport of animals, and by substituting public for private slaughter-houses, he demands that the full fury of the law should be turned on to scientific experiment, which must be totally abolished.

The demand thus made he bases on two grounds — (1) That nothing is necessary which is abhorrent to the general conscience of humanity, and (2) That it involves hideous injustice to innocent animals, quoting with approval Miss Cobbe's, in this case, specious axiom, that the minimum of all possible rights is to be spared the worst of all possible wrongs.

How far either of these arguments is applicable here we propose to briefly touch upon.

In the first place no proof whatever exists that scientific experiment is abhorrent to the general conscience, seeing that England is the only country where it is even under legislative supervision, that there, after the most careful deliberation, it is freely allowed on good cause shown, and that the whole body of those qualified to

judge strongly advocate it. Supported, therefore, as we have shown it to be, by the legal and moral sanction of the civilized and scientific world, it follows that the "general conscience" of which Mr Salt speaks must find its local habitation in the minds of a class of persons about as enlightened as those who fomented the riots against the study of anatomy, a noisy and violent agitation, which has died the natural death of ignorant prejudice.

For the refutation of the second proposition, viz. that of the cruel *wrong* done to an innocent animal by sacrificing it for the good of others, we must refer Mr Salt to his own principle of animals' rights, in which the freedom conceded to them to live their own lives is very properly made "subject to the limitations imposed by the permanent needs and interests of the community," and we fail to see how the logical application of an acknowledged right can be supposed to involve the infliction of a "cruel wrong."

The contention of the scientific experimentalist is exactly that which is here conceded by Mr Salt, viz. that the interests of individuals of the lower race must morally be treated as subordinate to those of the higher, and that while men are bound to benevolently regard all harmless animals, and never to inflict pain upon them wantonly, they not only may but ought to do so when the suffering thus caused is but one-tenth in intensity and one-millionth in quantity of that which it is designed to avert from both mankind and the lower animals. The whole matter is in truth a rule of three sum, and unless the anti-vivisectionist can successfully demonstrate that the scientific statement of accounts is false, his outcry is but the confession of the immoral fact that, rather than inflict an infinitely less amount of physical suffering upon some individuals of a lower race, he wilfully prefers to perpetuate a far greater amount of both physical and psychical agony among the whole community of animals and men. When such an avowal of callousness can be seriously advanced in the name of humanity we are tempted to believe that chaos is come again.

We should not omit to mention that Mr Salt appears to be an ardent republican, and that he looks for the advent of his animal millennium upon the establishment of an "enlightened sense of equality," but whether of men with animals, of both with insects, or all three with bacteria, he does not say, nor are we concerned to enquire.

#### ELEMENTARY PHYSIOGRAPHY

*A Description of the Laws and Wonders of Nature*  
By Richard A. Gregory, F.R.A.S. (London: Jos. Hughes and Co.)

NOTWITHSTANDING the numerous text-books that have been issued from time to time on this subject, it seems to Mr. Gregory that there is still room for another, for whose appearance, however, he apologizes and offers an explanation.

A work on physiography is not, as some people, who ought to know better, seem to think, limited to the study of physical geography. At least that is not the view, the author emphatically asserts, of Profs. Judd and Lockyer,

whose opinion in this matter is final for the students interested. Neither is it a work on astronomy, nor chemistry, nor geology, nor any specialized science, whose aim and scope are recognized and defined, though doubtless it is allied to all. As soon as an author treats of any of these subjects in detail, he is travelling beyond the record. To this fact Mr Gregory is fully alive. His object, if we have understood him correctly, consists rather in showing that some knowledge of all branches of physical science is necessary for the pursuit of one, and this kind of general knowledge he considers comprised under the generic term, physiography. It is the kind of information which every so-called educated person ought to possess, and without which he is not educated.

It may not seem a very ambitious task to write a book to meet the requirements of a syllabus, and our author thinks it necessary to defend himself against the charge of producing a cram book, addressed to the few ambitious of possessing a South Kensington certificate. But the task need not be the less useful or the less necessary on that account. Indeed, there is one circumstance connected with the appearance of this book which is very satisfactory, and should be a subject for congratulation. The author asserts that the book is rendered essential from the fact that the examiners have found it necessary or desirable to raise their standard for examination. This means that the Department has proved, that the general character of the education given to those classes from which the candidates for examination are drawn has so improved that a greater amount of information can be demanded than was formerly the case.

But independently of the fact that the author addresses himself principally to those preparing for the ordeal of examination, he has produced a very readable book, a little too much like an encyclopædia perhaps for ordinary tastes, but replete with a vast deal of information, by no means ill-arranged and generally expressed with exactness, but the effort to impart and to treat lightly and discursively of many branches of information is apt to give to the book a disconnected and incoherent aspect, and this is the principal defect that can be urged against the work. As soon as a subject is introduced it is necessary to drop it, because to pursue it in detail would be to enter into the domain of some science whose limits are fixed, and to which further discussion properly belongs—for instance, we have a chapter on water (its composition and different states), which it might seem very desirable to pursue at greater length, but as soon as the student gets interested, without a word of warning the subject is dropped, and he finds himself introduced to the method of measuring angular space and time. This naturally leads on to some preliminary account of astronomy and astronomical methods, ending with the measurement of the day and year, and then, on turning the page, the reader is not allowed to continue the subject, but is invited to consider the composition and characteristics of common rocks. This incoherency is perhaps inseparable from the subject; but we think the author might have developed his introductory chapter at greater length and put his scheme and sequence of thought more fully before his reader, so as to prepare him for these sudden deviations from continuity.

It is instructive to notice that as educational treatises are improved in character and prepared by those qualified for the task, the reverent superstition which has for ages surrounded certain errors and fallacies, that have done duty for scientific reasoning, is being remorselessly swept away. The so called proof of the sphericity of the earth, based upon the fact that ships have sailed round it, is not quoted now, even by incompetent teachers, with the same satisfactory conviction that was formerly accorded to it. Mr Gregory gives a diagram which ought to convince the most antiquated schoolmistress, but such myths die hard. Similarly with our friend "the burning mountain," which has frequently been regarded as an adequate definition of a volcano—that too is meeting with its deserts, but this will take a still longer time to kill, let Prof. Judd and others insist as they will. Many instances will occur to every one who has compared the carefully compiled text-books of to-day with those that were popular only a few years back, and no fact marks more emphatically the improvement, or the necessity for improvement, in educational treatises. Definitions, to be accurate and adequate, will always be a source of trouble to the writers of elementary books, and the author of the present work has no doubt been exercised to combine the necessary accuracy and simplicity. We cannot think that he has always been happy, but where so much is admirable it would be ungrateful to dwell upon small blemishes, and can only be permitted with the view of securing their improvement or removal in a future edition.

The definition of meridian as given on page 105 and again at page 151 is susceptible of improvement, and it is certainly incorrect to describe a sidereal day as the interval of time that elapses between two successive transits of the same star. Such little slips must be due to the hurry of production, as that on page 382, where we are told to determine the position of the north point by observing the "shadow of the sun." We should have thought the shadow of the object would have been more convenient. And again, on page 407, what is meant by the sun's "regular diameter"? But such little slips as these do not materially detract from the merit of the book, which we heartily commend to the thoughtful study of those for whom it has been written.

#### SCIENCE AND BREWING

*A Handy Book for Brewers* By Herbert Edwards Wright, M.A. (London: Crosby Lockwood and Son, 1892.)

THE author claims that the principal aim of this book is to give the conclusions of modern research in so far as they bear upon the practice of brewing. We gathered a different opinion on first opening the volume, for facing the title-page there stands conspicuously a trade advertisement of a firm manufacturing a patented article used by brewers, stating that this article is "referred to in the work," and "for further particulars see advertisement at end of book." To any one at all familiar with the way in which quasi-scientific articles are so frequently to be met with in the literature of brewing written for the purpose of advertizing their author or some other thing, it would be only natural to conclude

that the advertisement quoted was the real clue to the origin of this volume, and wonder at the unusual clumsiness with which it was made so evident. However, we afterwards meet with the following statement in the author's preface: "Having found after the sheets had been finally passed to the printer, that the publishers considered it would be a useful feature in the book to insert a few advertisements of matters interesting to brewers, he wishes it to be clearly understood that he has no personal interest in the matter." A little prejudice perhaps remained in our mind even after reading this disclaimer, but in justice to the author we may say at once that a perusal of the book has removed it. We sympathize with him in having a publisher whose disinterested over-zeal for the convenience of his readers has given his book such an unpleasant first impression.

From a scientific point of view, in one respect the practice of brewing compares with the practice of medicine, in that the complexity of vital processes has to be encountered in both, and through our present imperfect state of knowledge of these questions, the practice of both is based very largely on empiricism. Fortunately for the brewer, the life functions with which he has to deal so largely belong to the more simple forms of life, and the vast strides which have been made the last few years in our knowledge of the microphytes, and the physiological processes of the higher plants, have probably placed him much nearer to a sound scientific basis on which to rest his practice, than is the physician who has to deal with the vital functions of the most highly developed organism. But even yet empiricism rules many details of the brewer's practice, although research is gradually throwing true light upon them, therefore any writer who, in the present state of things, attempts to bring scientific knowledge and the practice of brewing together, has a very hard task before him in order to clearly make his readers understand the relative position in which the two stand at present. Mr Wright has with much diligence gathered together the results of a large amount of research work bearing upon the different stages of the brewing process, but we do not think that he has been always happy in selecting only the most trustworthy of these, neither are we pleased with the way in which he sets them before his readers to explain, or at any rate throw light upon, the different stages of the manufacturing process. It is a very difficult task, as we have just intimated, and we believe that the author, who is evidently a scientific man as well as a practical brewer, could have improved upon these parts of his work; at any rate we are quite sure that with due consideration he could easily have improved upon the general arrangement of his subjects, which is badly considered, and must be very confusing to a student not well acquainted with his subject.

We also regret that space is wasted in devoting a chapter to an attempt to teach the science of chemistry to the reader. Some such mistaken attempt is frequently made in technical works treated scientifically, but a greater waste of paper can hardly be imagined. For instance, in the present case we have a chapter starting with a description of the elements and the atomic theory, which positively, in less than thirty-five pages, professes to lead the reader up to the consideration of the con-

stitution of the carbo-hydrates and the amido-compounds. What can be the use of this sort of writing, however well done? No student not already well grounded in science generally can hope to get any real advantage from those parts of this book that are devoted to the scientific consideration of the details of the brewing process, and we wish the author had boldly recognized this very evident fact.

Apart, in a manner, from the more scientific portions of his book, the author gives us his views on the empirical questions of brewing, and also on the arrangement of a brewery and its plant, with the authority of much experience. Here is common ground on which all interested in brewing meet, and we recommend the author's conclusions as worth their attention. At the end of the volume we find a novel feature in a synoptic table of the malting and brewing processes, giving side by side the time, working memoranda, physical changes, and chemical changes of each process, an epitome which is likely to be useful to many readers. A good index also adds value to the book.

Although we do not think that the author in writing this book has been very successful in meeting the requirements of young students of brewing, yet there is a large amount of information contained in the 516 pages of the volume which will repay a careful perusal by those more advanced in the study of the scientific aspect and practice of brewing.

#### OUR BOOK SHELF

*A Manual of Veterinary Physiology* By Vety-Captain F Smith, M R C V S (London Baillière, Tindall, and Cox, 1892)

THE publication of this work ought to delight the heart of the veterinary student, for hitherto in his pursuit of physiological knowledge he has been compelled to rely upon works which deal exclusively with the human subject. However excellent such works may be and well adapted to the requirements of the human physiologist, they must necessarily contain much which is only of secondary importance to the veterinary student, and absolutely nothing concerning many questions which to him are of vital interest. For example, how needful to him is a thorough knowledge of the physiology of the horse's foot—the seat, as he is afterwards to learn, of manifold diseases. Yet clearly the consideration of this subject is outside the range of human physiology. Similarly the composition, digestibility, and feeding properties of the foods supplied to the various domestic animals are to him matters of paramount importance. Yet here again he finds himself left in the lurch by the standard works on human physiology. Such considerations amply indicate the necessity for a work of the kind now before us, and cause us to wonder that the veterinary profession should have had to wait so long for its publication. Though several first rate treatises on veterinary physiology exist in French and German literature, Captain Smith's is the first attempt, we believe, to deal with the subject in its entirety in this country.

We can heartily congratulate the author on the manner in which he has performed his task. He writes in a concise but precise style. Bearing in mind how many subjects the student is supposed to take up and master in a comparatively short time, the author has omitted, and we think wisely so, the details of physiological experimental methods and descriptions of elaborate mechanical appliances employed in the laboratory.

The value or usefulness of the horse depends so largely

upon its powers of speed or draught that a knowledge of its locomotory apparatus is obviously imperative to the veterinarians. During recent years much light has been thrown upon the subject of animal locomotion by the elaborately devised experiments of Stillman and Muybridge, carried out, as is well known, by means of instantaneous photography. Captain Smith furnishes a capital *résumé* of the conclusions derived from these experiments and a number of plain, simple diagrams aid the reader considerably in comprehending the subject.

The physiology of the horse's foot is dealt with in a somewhat short chapter. The author adheres to the theory of the expansion of the foot at its posterior part when the weight of the body is imposed thereon. It is a subject which has often been hotly debated, and its discussion will probably be again reopened in the columns of the veterinary periodicals. The chapter concludes with some half-dozen rules on physiological shoeing, a copy of which might well be suspended and acted upon in every place where the shoeing of the horse is carried on.

The book is well printed, neatly bound, and published at a very reasonable price (10s 6d). Horse-owners as well as veterinarians will find its perusal attended with profit as well as interest. W F G

*The Principal Starches used as Food* By W Griffiths (Cirencester Baily and Son, 1892)

THIS little book of 62 pages will be found useful by analysts and others who are interested in the examination of foods. The author has collected together short descriptions dealing with the origin and microscopical characters of the different starches met with in commerce—the arrowroots, tapioca, sago, the starches of our common cereals, and of millet, maize, rice, the bean, the pea, the lentil, the potato, and so forth. These are classified according to the natural orders of the plants from which they are derived, and the descriptions are accompanied by remarkably good photo micrographs, which indicate at a glance the peculiarities of the different varieties. The mode of classification serves to bring out the resemblances which often exist in starches obtained from plants of the same natural order. Since the microscope alone can be employed in attempting to trace the origin of a starch, and bearing in mind the extent to which it is now used as an adulterant, this handy little book will no doubt supply a want.

Three clerical errors were noted. On p 47 "feint" should be "faint," and "not" is evidently omitted in line three from the bottom. On p 48 "character" should be "characters."

*Les Alpes Françaises* Par Albert Falsan (Bibliothèque Scientifique Contemporaine (Paris.) B Baillière et Fils, 1893)

WE cannot call this a successful book. A mixture of condensed statistical information and of popular descriptive writing is not much better than a strabout of Liebig's extract and of trifle-whip. Fixity of purpose on the author's part is also wanting. Doubtless the French Alps cannot be separated from the rest of the chain, but for a book of only 286 pages all told, this contains too much about the Central, Pennine, and Eastern Alps. The geological part is sketchy, and not always very accurate. The author repeats the old mistake about the "variolite of the Durance forming a fringe to the euphohide," though the question was settled by the elaborate paper of Messrs Cole and Gregory, published in the *Quarterly Journal* of the Geological Society in 1890. The illustrations are numerous, few, however, of them are good, and several very bad. There is no index. The work, in short, is a piece of book-making, characteristically French in style, and is not a valuable addition to the library either of the mountain-climber or of the man of science.

## LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

## The New Comet

THE comet discovered by Mr. Holmes on November 6 was observed here on November 9 at 5h 50m, and found to consist of a very bright circular nebulosity with central condensation. The diameter of the comet was 5' 41".

It was re-observed on November 16 at 10h 45m, and its physical appearance seemed to have undergone a complete transformation. The diameter had increased to 10' 33", and the cometary material had become much fainter and more irregular. The nucleus was now in the form of a bright streak, and this was enveloped in a large faint coma. A small star was seen just N of the W extremity of the nucleus, and the latter seemed composed of knots of nebulosity.

On November 19, 14h 15m, the comet was seen again. Its general aspect was much fainter, and it exhibited a further increase in dimensions. I carefully determined its diameter as 14' 30", but the outlying portions were very tenuous and indefinite.

From Berberich's elements given in Edinburgh circular No 33, it appears that the comet is moving rapidly away from the earth. The great increase in its apparent diameter is therefore not a little remarkable. On November 9 the comet was about 203 millions of miles distant from the earth, and its real diameter must have been 333,000 miles. On the 16th this had increased to 652,000 miles. By the 19th the comet's distance had become 217 millions of miles, and its real diameter 925,000. In ten days, therefore, the cometary material expanded nearly threefold.

## The Light of Planets

A FEW facts relative to this subject may be interesting. At Plymouth on August 12, about 9 o'clock, favoured with a beautifully clear horizon, the brilliancy of Mars was so great that it cast a distinctly black shadow on a piece of white paper from an ordinary walking stick held at a distance of 4½ inches, the outline of the hand, under the same conditions, was also easily perceptible. A faint, yet decided, darkening of the white cliffs of the shore was caused by a person standing upright—the slope being about 45°. The point of observation was at the extreme north-west of the Sound, and the splendour of the planet's light reflected from three or four miles of water is perhaps unvalued.

The light of Jupiter has often enabled me, when using the telescope at a southern window, to make drawings and such references to books, &c., as were found necessary, without any other illumination.

JOHN GARSTANG.

Rutherford Measures of Stars about  $\beta$  Cygni

IN order to prevent any possible misapprehension in connection with your notice (NATURE, vol. xlv. p. 619) of Mr. Rutherford's measures of the stars surrounding  $\beta$  Cygni, may I call attention to the following?—The two stars of Argelander, 27 3435 and 28 334, concerning which a doubt is expressed in my paper,

are certainly lacking on the Rutherford plates. If they were present they would be very near the edges of the plates, and it is for this reason that I doubted whether we should expect to find them at all. The star numbered 28 in the Rutherford list, which appeared only as a sort of elongation of No. 27 on a plate taken at this Observatory, April 19, 1892, is one of the components of  $\Sigma 2539$ , as was pointed out by Mr. Burnham in the *Astronomical Journal*, No. 268, and by myself in the same journal, No. 266.

The Alleged "Aggressive Mimicry" of *Volucella*

MR. POULTON's letter calls for few words in reply. I invited Mr. Poulton to produce observations in support of his statement that the two varieties of *Volucella bombylans* lay in the nests of the bees which they respectively resemble. To this invitation Mr. Poulton has not responded. He tells us that his account represented "a very general impression", that the same impression has been set forth in a showcase at the Museum of the Royal College of Surgeons, that even if he were mistaken it was well, if through his mistake the truth shall the more abound. It is thus admitted that in making that statement Mr. Poulton relied not on original authorities, but on the general impressions of others. That these impressions are in any sense correct there is as yet no evidence to show.

Compared with this, Mr. Poulton's error as to *Rombus muscorum* is of course comparatively trifling and it would be useless to pursue the matter, were it not for discoveries made in the process of unravelling it.

I pointed out that *V. bombylans* is common in nests of *B. muscorum*, a bee which it does not resemble. Mr. Poulton in reply maintains the opinion that *V. bombylans* var. *mystacea* does resemble *B. muscorum*. In defence of this statement he refers to (1) the showcase at the Royal College of Surgeons, where the resemblance is set forth, (2) a recent book, "Animal Intelligence," by Mr. Lloyd Morgan, where the resemblance is again asserted and illustrated by figures of insects in the similar showcase at the Natural History Museum.

In following up these clues I came to unexpected results. (1) There is at the College of Surgeons a showcase, as stated, illustrating the likeness of *Volucella* to humble bees. The label states that "the resemblance enables them [the flies] to escape detection." Two bees are exhibited bearing a good likeness to the var. *mystacea*, and, as Mr. Poulton says, they are labelled "*B. muscorum*." The one, however, is a worker of *B. sylvarum* L., and the other is probably a male of the same species. Neither can be mistaken for *B. muscorum*, which they do not resemble.

(2) At the Natural History Museum bees of several species are shown beside the *Volucella*, with a similar statement that the resemblance enables the flies "to enter the nest of the bee without molestation." Not one of these bees is *B. muscorum*, nor are any of them said to belong to this species, for no names are given. Nevertheless, on turning to Mr. Lloyd Morgan's book, which I had not before seen, I find the statement (p. 90) that *V. bombylans* "closely resembles" *B. muscorum*, the passage continuing in the words of the Natural History Museum label. Figures are added showing the two forms of *V. bombylans* and two very different bees, both marked "*B. muscorum*." Now the figures are from photographs of certain specimens in the showcase, and on reference to the specimens in question, it appears that one of them is a yellow-banded humble bee (perhaps *B. hortorum*), while the other is one of the red-tailed humble-bees! These two are put out to match *V. bombylans* and the var. *mystacea* respectively, and of course have no likeness either to each other, or to *B. muscorum*, though both are referred to this species by Mr. Lloyd Morgan.

Mr. Poulton's choice of *B. muscorum* as a form resembled by the var. *mystacea* probably therefore arose from the wrong naming at the Royal College of Surgeons. How Mr. Lloyd Morgan came to call the two different bees by the name *B. muscorum*, which belongs to neither, I cannot tell. Perhaps this is in part an echo of Mr. Poulton's previous mistake.

Any one by reference to a collection of bees may easily satisfy himself that the common and ordinary *B. muscorum*, with its bright brown thorax, does not resemble *V. bombylans*, though this fly is common in its nests, just as *V. pellucens* lives in wasps' nests, though it does not resemble a wasp.

In the absence of direct evidence in its favour, and inasmuch

as it is inconsistent with many ascertained facts which were specified in my first letter, the hypothesis of "Aggressive Mimicry" should surely be withdrawn.

No speculation is needed to enhance the exceptionally interesting facts of the Variation and the resemblances of the *Volucella*. If a number of people will set to work on this problem in the way suggested, there is, I think, a fair chance of considerable results. It was in the hope that such effort may be made that I drew attention to the matter, and I am really sorry that Mr Poulton should be hurt thereby. Nevertheless, I cannot but regard his account of the matter as an example of the way in which statements pass on from one writer to another, but prove on inquiry to be baseless.

WILLIAM BATESON

St John's College, Cambridge, November 14

#### Parasitism of *Volucella*

MR BATESON's interesting discussion of the relations between *Volucella* and the species of *Bombus* (NATURE, vol. xlvii p. 585) suggests the following observations.—The nest of *B. muscorum* is made without much effort at concealment on the surface of the ground. If accidentally disturbed the inmates set up a peevish buzzing, which, no doubt, answers the purpose of warning off ordinary intruders. Yet *B. muscorum* is of a patient and gentle disposition, and will put up with a good deal of maltreatment before using its sting. Its sting, moreover, is less venomous than that of either of our other common humble bees. It apparently trusts to the reputation of its genus for protection from annoyance. Such a creature would seem marked out by Nature as the very host to be imposed on by a parasite like *Volucella*, which, on the other hand, may need all its cunning to come round an irascible being like *B. lapidarius*, or even like *B. hortorum*. And, in fact, as Mr Bateson points out, we find it multiplying abundantly at the expense of the first named bee, and less frequent in the nests of the other two. Notwithstanding this, *B. muscorum* appears to be certainly no less successful than either of the others in the struggle for existence.

#### Optical Illusions

THE illusion of the Gothic arch in NATURE (vol. xlvii p. 31) is too good to have a rival, but simple Norman arches occasionally practise a deception of some subtlety. In certain cases they seem to be of the Moorish horse-shoe form, this happens when the semicircle does not spring at once from the capitals of the Norman columns, but has a short intervening vertical space of masonry. Architects are familiar with the effect, and call these arches stilted; they say the stilts are commonly vertical, although Norman walls have no doubt sometimes fallen away from the upright course. I suppose the eye is quick enough to perceive that there is more than a semicircle, while the mind is gullible enough to infer that the curvature is continued. In Winchester Cathedral there are some good illustrations of this appearance.

#### A Strange Commensalism—Sponge and Annelid.

A CURIOUS case of what I believe to be definite commensalism between members of these two classes came under my notice the other day when collecting, and, as it is, so far as I know, a new instance in this interesting inter-relationship between animals, I venture to record it.

Several large patches of crusting orange red sponge attracted my attention because of the peculiarly emphatic markings of what appeared to be the oscula. They were suspiciously unlike anything spongiform, so I secured some good pieces of the sponge for further investigation. Sections proved them to belong to the *Microciona plumosa* of Bowerbank, but the supposed oscula—which to the naked eye appeared as innumerable tiny black specks, each surrounded by a grey ring—proved to be, when the mass was teased out in water, in reality the ends of tubes inhabited by an eyeless *Leucodora* (*L. caca*, Cératid). Fully forty could frequently be counted in a square inch.

The conclusion I come to after examination of a large number of specimens is that actual benefit is mutually given and received by each of the two mesmates, the sponge gaining considerable support and extra consistency from the numerous comparatively wiry upright tubes. There is also the question whether the excreta of the worms is of any food value to the sponge. On the part of the worm, there is little doubt that it finds a valuable

protector in the sponge which by the way is characterized by an intensely rank smell of garlic (warning odour?). I have seen no signs of this sponge being preyed upon by any animal, so we may conclude its protective devices of spicules, odour or taste are fairly successful. A worm whose tube is sunk completely in its substance will naturally be very safely housed, and besides, the friendly water currents set in motion by the sponge cilia will bring much food matter to its very mouth.

Bowerbank in his description ("Br Spongiadae," vol. ii p. 134) writes of a specimen as "permeated by some small tubular zoophyte which it has coated with its own tissues, and from these adopted columns defensive spiculae are projected"—evidently the same as I describe above, though he makes the mistake of considering the tubes as those of zoophytes instead of those of annelids. From this quotation, however, it is evident that the habit is widely spread, and not merely local. Here at extreme low-water the sponge grows exceedingly abundant, and the commensal worm seems always present.

JAMES HORNE

Jersey Biological Laboratory, November 10.

#### Induction and Deduction

MR DIXON says that there are "at least three different kinds of interpretation which may be put upon the proposition, [An isosceles triangle has equal angles at the base]. It may mean (1) the triangle used to illustrate this proposition has equal sides, therefore it has equal angles, or (2) I have conceived a triangle which has equal sides, therefore I have conceived one which has equal angles, or (3) the connotation ascribed by the adjective isosceles implies the connotation 'having equal sides' [? angles]."

He goes on to observe that the difference between either (1) or (2), and (3) is "that this latter gives us no information about any real thing or concept, but only about what is implied by using certain terms," that is, about the connotations of "isosceles" and "having equal angles" ("equal sides" is of course a slip). But if connotation refers neither to the attributes of "real things" nor to "concepts" (which I suppose means ideas or notions) what can it be that we "imply" by using the terms *isosceles*, &c? If we do not mean things, nor attributes of things, nor ideas, do we mean anything which can convey or contain information?

In Mr Dixon's view the terms do convey information, but information which "clearly does not require to be based upon any real knowledge of things, but may be based solely on definitions of words." But must not definitions of words be based, in the last resort, upon knowledge either of things or of concepts—definitions of current words in some current sense, or even of strange words in strange senses—as e.g. if I say *Abacadabra* means *extra mixtra*, and *Triangle* means *abracadabra*, and all *abracadabras* are four sided, and so on? With such propositions I may certainly frame syllogisms and arrive at "symbolical" conclusions, though I cannot see that I shall be doing anything to convey information or to advance thought.

And when Mr Dixon says that the proposition "an isosceles triangle has two equal sides" has "wide applicability and usefulness" because we "often find things which can fairly be called isosceles triangles," it seems clear that he himself cannot have taken the proposition at starting in a sense purely "symbolic" (in his meaning of that word). If he did, it would be little less than miraculous that an entirely arbitrary definition should happen so to fit actual experience, especially when we consider that other equally symbolical mathematical propositions have an equal applicability.

I think it is probably true that we often do not depend, for our assent to complicated reasonings, on anything like full "realization in succession of the actuality of the relations and operations discussed", but I cannot admit that such reasonings do not refer to objects of experience or of thought. Unless the terms did refer to something other than themselves, we could never assert  $S$  is  $P$ , or  $x = y$ .

I unfortunately know nothing either of Pascal's theorem or of the intersections of two conics, but I think that in the case of the individual isosceles triangle, my intuition that the equality of angles at the base is inseparably connected with equality of sides, gives me ample ground for believing it to be "mathematically certain" that every isosceles triangle has equal angles at the base; it is self-evident that the one characteristic cannot exist without the other. That the isosceles triangle in question, if put under a microscope or tested by some micrometer, might turn out to be not "really" isosceles, seems to be a perfectly

irrelevant consideration, and I have never been able to understand the stress laid upon it by acute thinkers. It is because the triangle is as far as I can perceive isosceles, that I intuit it to be as far as I can perceive equal angled.

It has, I believe, been already explicitly recognized by certain logicians that a "symbolically" proved conclusion need not give any actual information about "real things." Indeed some go further, but I do not know that any have gone so far as to say that it would not give any information about ideas—although perhaps this may be the logical conclusion.

### On a Supposed Law of Metazoan Development

UNDER the title of "The Relations of Larva to Adult Forms," I recently read a paper before Section D at the Edinburgh meeting of the British Association. The subject dealt with was of so extensive a nature, and the time available was so limited, that I fear much that was said must have appeared vague and ill-founded, if not entirely incomprehensible. The material of the essay had, indeed, been prepared with the intention of devoting at least an hour to its delivery as it happened, I found myself under the necessity of cutting out whole passages of my notes whilst speaking.

The few lines of the report in *NATURE* (vol. xlvii p. 404), convey a very inadequate idea of what I aimed at proving in the paper, and hence I am tempted to offer a fuller account to the readers of this journal.

The subject of the essay furnishes a problem which must interest every embryologist, even though he should reject the conclusions to which observation and reflection have led me.

In working out the complete paper so many novel and confirmatory points have been met with, so much of importance in the writings of the older embryologists, and more especially in the memoirs of Johannes Müller on the Echinoderm larva, has been unearthed, that an extension of the original plan of the work has been rendered necessary.

My conclusions, moreover, are so much in conflict with prevailing doctrines that any haste in producing the full argument would be unpardonable, although a preliminary sketch by way of clearing the ground may be justifiable. On a subsequent occasion an attempt would be made to show how the researches of recent years had, with a few notable exceptions (such as the work of R. S. Bergh, J. Kennel, and N. Kleinenberg), tended away from rather than in the direction of a recognition of the fundamental fact of an alternation of generations as underlying Metazoan development, in that they had been concerned, for example, with unnecessary attempts at homologizing the "mesoderm" and its mode of formation throughout the animal kingdom.

If the facts in support of my case should not be as complete as the published researches of the last thirty years on the ontogeny of very many animals might lead one to anticipate, the circumstance would have an obvious explanation.

With the death of Johannes Müller—a man whose brilliance as an embryologist was only surpassed by his greatness as an anatomist—there closed one chapter, and that one of the finest, in the history of comparative embryology. What influence the publication of "The Origin of Species" had upon the subsequent progress of the science is too well known to need further expatiation here. The pernicious search after pedigrees,

initiated by Haeckel, led to an era of activity during which every fact with no apparent bearings on phylogeny was ignored. As a consequence the work of Müller on the Echinoderm larva and the essay of Steenstrup on "Alternation of Generations" became more or less mere curiosities in the history of the science. With little exception embryological speculation of the past thirty years has been naught else than a pursuit of will-o'-the-wisps.

It behooves us now to revert to the path along which Johannes Müller laboured.

My own embryological conclusions, like those of contemporaries, have not hitherto been influenced by the embryological works of Müller, for it was not until after my paper had been read that a first study of the Echinoderm memoirs convinced me how nearly he had anticipated what follows.

Before passing to the subject, one further remark may be permissible. Owing to lack of time when reading the paper, no opportunity offered itself for pointing out the analogy which obtains between the suggested mode of Metazoan development and the accepted fact of an alternation of generations in the life histories of all plants above the lowest Thallophytes. Furthermore nothing was said about the mode of formation of the "mesoderm" in certain cases as one or more outgrowths of the endoderm, although the writer was fully alive to the explanation which from his standpoint could be offered. This and other questions of a like character would receive consideration in the complete paper, in which it would be demonstrated that such things and processes need be neither "palingenetic" nor "cenogenetic," but that the analogy of the formation of imaginal discs in *Insecta*, or in the *Pilidium* of the Nemertine, ought to suffice to account for them. As an instance, the formation of the mesoblastic somites in *Amphioxus* as evaginations of the endoderm may be only a mode in which certain parts of the adult are in that particular case laid down upon the larva.

And now, after this digression, to return to the question under consideration. Two modes of development have long been distinguished, viz., *larval with metamorphosis* and *fetal and direct*. Cases are known in which there subsists no homology between the larva and the adult, and even such in which the larva (*Bipinnaria asterigera*) is said to exist apart for a time after it has given rise to the Echinoderm. In many such, moreover, the sole larval organ carried over to the adult is the alimentary tract, all other organs of the larva, such as nervous system, sense organs, locomotor and excretory organs, mouth and anus, &c., being replaced by new formations in the adult. The new organs are thus not homologous with those of the larva, in deed, neither as a whole nor in its parts is the larva the homologue of the adult form, but the latter arises upon the former by a mode of asexual generation.

The birth of the Nemertine on the *Pilidium*, and that of the Echinoderm upon the *Pluteus*, or upon the *Bipinnaria asterigera*, may be cited as examples, and the question may now be asked, What becomes of the larva when (a) food yolk is more or less abundantly acquired, and (b) when uterine development is initiated? Does the larva really disappear? Anticipating the sequel, it is asserted that the larva never vanishes from the development, but is always present in more or less disguised form. In all cases the adult or imago would appear to arise upon it just as is so obviously the case in the examples previously cited.

In the complete paper the modifications of the process throughout the Metazoa would be considered, in this place generalities alone can be dealt with. If the larva be laden with food yolk it becomes transformed into a more or less obvious *blastoderm*, upon which the *imago* or mature form takes its origin. Certain of the larval organs—such as those of locomotion—may then disappear, but others, such as the larval excretory and nervous mechanisms (e.g., *Hirudinea*, according to Bergh's researches, *Ichthyopsida* from my own work) would persist. Considerations of space do not permit me to enter fully into details regarding Molluscan development. The published work on this group furnishes one with useful material in support of my case; and the group is an interesting one in connection with this question of the relation of the larva to a blastoderm. In the *Mollusca* one can readily find all gradations from cases in which the adult is gradually substituted for a pelagic larva (*Patella*), through those in which the larva is somewhat burdened with food yolk (*Buccinum*), to others, finally, in which there is a large yolk sac and a blastoderm, on which the adult form arises (*Cephalopoda*). Incidentally I may remark that it was the study of some *Buccinum*

larvæ (*Veligers* with large yolk-sac) three years ago, which first afforded me a key to the solution of the problem of the relation of the larva to food yolk.

The *Arthropoda* are an important group, for larval forms widely prevail, especially, as is generally admitted, in the lower forms.

The nature of the *Nauplius* is too big a question for discussion here, but Dohrn's conclusion that it is a transformed worm larva (i.e. one with *Arthropod* characters) appears to me to represent the truth. Two of the laws governing developmental processes appear to be that larval organs may be transferred to the service of the adult, and (more usually) that adult organs may become larval, or, as they may be termed, *adaptational larval organs*. Numerous instances of both these could be cited, and the three pairs of appendages in the *Nauplius* furnish us with a case in point.

In the development of *Mysis* there is an example of the conversion of the *Nauplius* larva, typically represented in the allied *Euphrosia*, into a blastoderm upon a yolk-sac.

I venture to attach most weight to the application of the principle to the *Vertebrata*, for it is there that my own work has chiefly lain, and it is undoubtedly the obstacles offered by the phenomena of Vertebrate development which have hitherto prevented the enunciation of the "law of development as an alternation of generations." Larvæ are so commonly encountered among the Invertebrata that the wonder is that no one has inquired why they are so rare, in any guise, in the *Vertebrata*.

In this latter division of the animal kingdom it becomes necessary to approach the problem previously stated as to the fate of the larva when uterine development is initiated.

It may firstly be noted that larval forms, equipped with many adaptational larval organs, are to be encountered in cases with complete segmentation and but little food-yolk, e.g. *Marsipobranchius*, *Ganoides*, and most *Amphibia*, while a blastoderm on a yolk sac is characteristic of *Elasmobranchius*, *Teleostei*, and *Saurapsida*, in which a larva, according to the common acceptance, would not be very obvious.

In all these cases, however, larval organs can be proved to exist, and, most important of all, there is a well-marked larval nervous system, which, while not certainly known to persist in any adult form, has been proved to degenerate during the ontogeny of all the oviparous *Ichthyopsida* as yet studied. This apparatus is certainly neither a part of the adult nervous system nor homologous with the latter. For an account of this mechanism the reader may be referred to the papers cited below.<sup>1</sup>

Among other larval structures referred to when reading the paper, the curious degenerating cells on the blastoderm of *Pristiurus*, to which Prof. Van Wijhe once drew my attention, and the knob on the blastoderm of *Torpedo*, as shown in Ziegler's beautiful models of the embryos of this form, and as described by H. E. and F. Ziegler in the *Archiv für Mikroskopische Anatomie*, Bd. xxxix, p. 85, deserve mention.

The yolk sac viewed as part of the larva would require detailed and extended consideration.

It is gradually broken down by some ferment action on the part of the so-called merocytes,<sup>2</sup> which may possibly represent degenerating cells of the larva. Only towards the close of life in the egg-capsule does the yolk appear to be digested by the alimentary tract of the Elasmobranch. In some reptiles, according to Hans Virchow, the remains of the yolk-sac would appear to be cast off.

In the discussion on my paper, one speaker, a personal friend, hinted that I had been led to look upon the yolk-sac as part of the larva from having followed some stray ends of "larval nerve fibres" on to that structure. I had to confess my regrets that at that time I was unable to lay claim to any such observation, indeed, that having cut my embryos of *Raja batia* without any part of the yolk-sac appended, it had never occurred to me that the fibres described might pass to the yolk-sac. Quite recently it has been seen that at any rate some of the larval "subepiblastic nerves" of the *Anat. Ans.* paper do undoubtedly make their way to the surface of the yolk sac, lying just beneath its epiblastic covering. That a further confirmation of my conclusions is to be found in this observation goes without saying.

<sup>1</sup> J. Beard "The Transient Ganglion Cells and their Nerves in *Raja batia* *Anat. Ans.*, 1892, pp. 201-206, and also, "The Early Development of *Lepidosteus osseus*," *Proc. Roy. Soc. London*, vol. xlv, 1889, pp. 215-218.

<sup>2</sup> As to H. E. Ziegler that we owe most of our knowledge of the way in which these merocytes, in their own degeneration and death, cause the elements of the yolk to become fit for absorption and assimilation.

Some three years ago, when considering the "Inter-relationships of the *Ichthyopsida*," at a time when this larval question was prominently before me as a fascinating puzzle, I thought that the larva disappeared above the *Ichthyopsida*. I was led to this conclusion by reliance on the accepted belief that larvæ are only met with in aquatic animals, more particularly in marine forms, and by the apparent absence of a larval nervous system above the *Ichthyopsida*. My recent studies and the work of Froriep and Robinson have taught me that this was erroneous.

The larva never disappears, however much it may undergo degeneration.

It may even be doubted if there are not traces of the nervous system of the larva in the ontogeny of the *Amniota*, for there appear to be certain observations of Froriep on reptiles which may admit of interpretation in this sense, and my friend, Dr. Arthur Robinson, tells me that he believes he has found traces of it in certain Mammalian embryos. In mammals, as will be seen, the larva must be regarded as an internal parasite, and like such it would yield up its chief organs. Some remains of its nervous system may, however, persist, as I have proved to be the case in *Mustelus vulgaris*, where the larva is almost as parasitic as in the Mammal. The *Amnion* of the higher Vertebrata is probably also a larval structure with analogies to the organ of the same name in *Insecta*, in the *Pholidium* development, &c., as Kennel had previously insisted. It would appear to me to be a membrane conditioned by the way in which the adult is formed upon the larva.

Another important larval structure is the yolk-sac placenta of *Mustelus larvis* and of many mammals.

In the latter the importance of this organ during a long period of fetal life has been proved by Hubrecht and Robinson.

The yolk-sac placenta may be explained as due to the fixation of a parasitic larva; indeed, in mammals the larva has become a fixed internal parasite in the uterus, and its mode of life, like that of all internal parasites, leads to great degeneration.

In this connection it may be insisted that it would be contrary to all that we know concerning the effects of the parasitic mode of life to suppose that a form might become a fixed internal parasite, and subsequently becoming freed from its host, attain to a higher grade of organization. Yet this is what we must believe to hold good, if the current views of mammalian development be accepted as correct. From my standpoint, on the contrary, the larva may become a fixed internal parasite, and none the less there may arise upon it a more highly organized and, when fully developed, free living form, the Mammal.

Witness must be borne to the circumstance that Muller, Kleinenberg, and Kennel have already recognized that in some few divisions of the Invertebrata the mature form always arises upon a larva.

In such groups as the Echinoderms an alternation of generations is now an obvious explanation of the facts, and when so magnificent an investigator as Johannes Muller proved this nearly fifty years ago, one asks, in vain perhaps, why modern embryologists, like Korschelt and Heider in their otherwise admirable "Entwicklungsgeschichte," ignore it. The "recapitulation theory," and the question concerning the nature of the mesoderm have overshadowed the fact and concealed the recognition of an alternation of generations. But the so-called "law of ontogeny" itself is no explanation of the riddles of embryology, at most the recapitulation hypothesis holds for the development of organs, not of organisms.

So far as the facts are available, Metazoan development appears to me to be by means of an alternation of generations, in that from the fertilized egg there arises an organism, the larva, upon which, in one way or another according to the circumstances of each case, a new form, the adult or imago, takes its origin.

In 1855 the veteran zoologist, P. J. Van Beneden, wrote — "*La génération alternante est un phénomène qu'il faut chercher à faire rentrer dans la loi commune de la reproduction et non pas laisser comme une exception dans la science*."

In this essay an attempt has been made for the first time to prove that it is "la loi commune de la reproduction" in Metazoa, and in concluding I cannot do better than echo the beautiful aphorism of Goethe, which in a similar connection has already been commented upon by Steenstrup and Von Baer: —

"Die Natur geht ihrem Gang, und was uns als Ausnahme erscheint ist in der Regel."

J. BEARD

<sup>1</sup> It is not assumed that all the phenomena classified as "alternations of generations" are alike in their nature.

EXPERIMENTS ON FOLDING AND ON THE GENESIS OF MOUNTAIN RANGES<sup>1</sup>

## Method of Investigation, Folding at Different Levels

DEFORMATION is represented in an exact manner, if we note the movements executed by certain

FIG 1

FIG 2

FIG 3

FIG 4

FIG 6

FIG 7

"

FIG 8

points, and the position of these points before and after deformation. I divide the surface of sediments into squares (scale = 0.1 m), and this division passes in

<sup>1</sup> Extracted from *Geologische und Geographische Experimente*, by Dr. K. Reyer, 1. Heft Deformation und Gebirgsbildung, Leipzig, 1892. See also "On the Causes of the Deformation of the Earth's Crust," by the same Author. (NATURE, vol. xiv, p. 224.)

vertical direction through the whole system, so that every stratum is divided into prisms or cubes of known dimensions and positions. At every moment of deformation we may note the movements of any point or line, and the deformation of any square or prism. Especially the deformations of the surface and of normal-profiles is important. The position (orientation) of prisms must agree with the direction of pressure.

I employed in every case muddy material (clay, plaster of Paris). Example. We note the position of prism I in Fig 1, and its position and deformation are noted in Fig 2, I is pushed forward and deformed into I r. B = the "Basal plane," is parallel to the base or surface. No = Normal plane, is situated vertical and in the direction of pressure. L = Longitudinal plane, vertical and at right angles with No, agrees with extension of strata.

N = normals,  $\epsilon$ , perpendicular scale-lines.

Explaining experiments. The sediments I, II, Fig 3 (exp. 203, clay with a layer of plaster) are subjected to lateral thrust. The higher parts are more moveable and get deformed more than the lower strata.

I goes to I r, it is compressed and elevated, II in contact with the wall is elevated a little (to r). The dark middle stratum I produces a flat fold. In Fig 4 compression and elevation is more intensive. The normals N (originally vertical lines) are deformed into curves.

When at the surface very plastic material dominates (mud), the surface after deformation remains flat, whereas in the deeper parts intense folding may have taken place. If we push a muddy mass, covered by plastic layers, the latter get folded, whereas the deep parts are only thickened.

The movements and deformations of N (normal profile) are of especial importance.

Fig 5 (exp. 292), paper between muddy strata. The direction and deformation of normals show the typical movement of strata in each case.

In Fig 6 a plastic layer (white) lies between muddy sediments. After the deformation only the white layer is folded.

In Fig 7 folding towards the deeper parts is more intense, but the muddy surface remains flat. In all these cases strata get thickened. The thickness measured in a fold-chain does not correspond to the original thickness. The strata of the Appalachian Mts., having to day a thickness

of 10 km in a certain section, originally had different dimensions. If measured along the fold-limbs the number is by far too small, as here the strata are rolled out, in the synclines, on the contrary, strata appear much thicker than they were at the beginning.

If plastic sediments are driven by their own weight,  $\epsilon$  if they glide over an inclined plane against an obstacle.

there occurs a deformation, as in the case of lateral pressure. Deformation in the first case is greatest near the obstacle

*Anticlinal Rupture, Pinch-folds, Squeezing, Pseudo-eruptive Processes*

Pushing produces compression. In the anticlines tension effects rupture. In the fold-limbs plastic material is squeezed, rolled out, and pushed towards the clines (synclines or anticlines).

In the synclines of great dimension plastic material is pushed together and pinch-folds result.

Passing over some of the experiments which illustrate the dislocations described by Heim and Margerie we come to more complicated examples.

Figs 5-8 show "pinch folds" in very plastic material, which are spread and thrust over, so that they form a flat bottom in the syncline.

Other experiments illustrate a pinch-fold with ruptural deformation. Usually the intense deformation is confined to the district of the pinch-fold, in very plastic material and under variable pressure the stratum in every part gets greatly altered. If we divide the strata into differently coloured prisms we see in each profile at once the deformation at every point. Often deformation is so intense that we may denote it as kneading.

The deformation shows how a vertical dyke gets influenced by folding.

If a plastic stratum is inserted between rigid strata, the former often gets injected into ruptures of the rigid sediments, mud-dykes, pseudo eruptive processes (Reyer, "Theoret. Geol." p. 330).

*Movements of Normals and of Waves Overthrust, Thrustplanes*

In a fold-chain the higher masses are pushed over the lowland, which does not yield sufficiently. The result is an overthrust, often combined with pinch-folds, Fig 11 (exp. 207). The inverted strata dip against the direction of the push.

Fig 9 = original thickness of strata. In Fig 10 folding begins. Fig 16 last stage. Normal measure at the base = 1 dm.

In most cases shifting occurs between the strata, especially in upheaved strata, and we see gaping fractures, which cross a stratum and then follow again the planes of stratification (intrusive sheets).

The gliding movement may sometimes cause an extrusion.

Fig 12 plan, and section Fig 13 (exp. 278).

An overthrust-fold is nearly squeezed off (compare position of normals). An intense thrust generates ruptures, and the strata glide in the form of scales over the lowland.

Fig 14 (exp. 242) a fault in the base, over which a complex of sediments glides, the lowland sinks and the higher masses now push with increased force towards the plain ("Vorfaltung" Suess).

*Squeezing and Tearing, Deformation of Included Masses.*

Squeezing and tearing often occur in regions of great difference of tension or pressure. In the anticlines strata are torn, the direction of ruptures is converging

towards the axes (axipetal direction), in the limbs there occur squeezing and tearing.

[In the latter part of his memoir, Dr. Reyher shows how his experimental methods may be applied to the explanation of such complicated questions as very complicated overthrust faults, the appearances presented when much folded and faulted strata are subjected to erosion, the occurrence of undisturbed tracts associated with much folded ones, and the formation of lake-basins.]

*GALILEO GALILEI AND THE APPROACHING CELEBRATION AT PADUA.*

ALTHOUGH Galileo began his career as a teacher in Pisa, and occupied for three years the Chair of Mathematics there, and was inscribed until his death in the list of the teachers of that University, nevertheless the University of Padua was the one to which from the beginning he had aspired, and in which he exercised with the greatest efficiency his powers as a man of science and

\* Compare the excellent experiments of Forchhammer (Sanddruck, 1882), Cadell (NATURE, vol. xxvii, p. 489). Those authors experimented with powder-material, whereas I operate upon plastic materials.

a lecturer. Now the University and citizens of Padua desire to celebrate the tercentenary of the day on which he delivered his first lecture.

When elected by the Venetian Republic to the Chair of Mathematics on September 26, 1592, he asked to be permitted to delay the beginning of his lectures in order to prepare his inaugural oration, and to attend to some domestic duties which required his presence in the country, thus it was December 7 when he first occupied the professorial chair. This date is confirmed by a letter, written from Padua to Tycho Brahe, and published by the latter in his celebrated "*Astronomia Instauratae Mechanica*," and Galileo's chair is amongst the most precious relics preserved by the ancient and famous University. A week later he began regular lectures, which he continued to give for eighteen years.

In the ancient archives of the University the rolls of the time when Galileo taught are in a great measure preserved, and from these we learn that, in accordance with what was prescribed by the statutes, he alternated astronomical teaching with that of Euclid and the mechanical questions of Aristotle.

The didactic activity of Galileo was not altogether confined to public teaching; it was extended, in conformity with the prescriptions of the statutes, to private teaching. How much influence he exercised in this manner is easily seen from his autographic records which have come down to us. The importance of these private lessons will appear all the greater when we reflect that they dealt not only with the subjects discussed in public, but with matters connected therewith. From contemporary documents we perceive with what precision all such subjects were taught by Galileo: the use of the geometrical and military compass, fortifications, Euclid, perspective, mechanics, geography, arithmetic, geodesy, and cosmography. As to the students, they were for the most part foreigners, namely, Poles, Germans, Danes, French, and Flemings. In the lists of private scholars we find an "illustrious Englishman"—very probably Richard Willoughby, who was vicar of the University of Law and Councillor of the English nation. In his honour a stone on the wall of the University is still preserved, and, a still greater honour, a copy of the famous "*Difesa*" is dedicated to him with Galileo's autograph. Two Scots should also be particularly mentioned as amongst Galileo's pupils, these were John Wodderborn, who wrote a confutation of the libel of Horky against Galileo, and dedicated it to Henry Wotton, the English ambassador at Venice, also Thomas Seggett, Councillor of the Scots nation, in whose "*Album Amicorum*," now in the Vatican library, there is also an autograph of the great philosopher. It was Seggett who received from Kepler a copy of Galileo's "*Sideteus Nuncius*," and who in the appendix to the "*Narratio*" of the same Kepler published the epigrams containing the famous "*Vicisti Galilae*."

Besides the ordinary public and private lectures, Galileo held in the University some special public lectures, of which we may mention those upon the new star of October, 1604, and those in which he announced his astronomical discoveries.

Every one tried to render Galileo's stay in Padua as pleasant to him as possible. His freedom in teaching was absolutely complete, and the strong arm of the Venetian Republic defended the professors of the University from the power of Rome. In Padua, from the first, Galileo was received with the greatest kindness, he found many faithful friends both in Paduan society and among the Venetian patricians. His salary was repeatedly increased, so that, after the presentation of the telescope, it rose to thrice the amount conceded to his predecessors. Galileo came to Padua at the age of twenty-eight and remained there during the eighteen years which were the best of his life, those

in which he showed the greatest scientific fertility, and in which he prepared the way for all his future labours. We have now reached the completion of the three centuries since Galileo began his teaching in Padua, and the University naturally considers that the anniversary should not be allowed to pass without honourable notice.

It is fitting that a celebration relating to the work of a man of science of the highest rank should have a truly national character. The King of Italy has therefore associated himself with the movement, and the Universities, the polytechnic institutions, and the most celebrated academies of the world have been invited to send delegates. Already the Universities have in great number responded to the appeal. Mr J. Norman Lockyer will represent the Royal Society of London, and Mr George Howard Darwin the University of Cambridge.

As once scholars from every part of Europe came to Padua to hear the celebrated master, so now from every part of Europe the most celebrated come to honour his memory.

ANTONIO FAVARO  
(Director of the National Edition of Galileo's Works)

#### A NEW METHOD OF TREATMENT FOR CHOLERA

IN the *Times* of the 18th inst. there appears an account of a new method of treatment for cholera which, should it ultimately be proved to be founded on accurate observation and well-authenticated cases, gives results seldom, if ever, obtained by any other method during the height of a cholera epidemic. Before criticizing this new method let us see what are its essential features.

In cholera there are two main, and evidently different, indications for treatment: it is usually maintained that the primary etiological factor in the disease is the "Comma" bacillus, which under certain conditions is enabled to live and multiply in the human intestine. There, living as an anaerobic organism, it thrives especially well if, through inflammatory reaction, certain of the albuminous constituents of the blood and lymph are thrown into the intestinal tract. From or in this favourable culture medium it is enabled to produce a most virulent and readily diffusible poison, which has not only a powerful local action, but also a power common to these micro-organismal poisonous products, of acting on the nerve centres. In this way, so long as the bacillus remains alive, the supply of exudation into the intestine is kept up by the local irritant action of the poison, this being accompanied by a rapid abstraction from the blood of its watery elements, and at the same time a supply of the powerful "toxine" is maintained and diffused throughout the body. Except in very severe cases, where the paralyzing effect of the toxine on the individual cells of the tissues is extremely rapid and well marked, an effort is made by these cells to destroy the bacilli and by the special secretory cells of the intestine, kidney, and other excretory organs to eject this poison from the body. Not only so, but if the poison can, like the bacillus, be confined to, and eliminated directly from the intestine, the bacillus soon becomes unable to live, and as it multiplies and produces its toxins it is killed off by the various agencies that are conspiring to destroy it.

Up to the present all conceivable methods of treatment have been tried, and almost every drug has been pressed into the attack on cholera, but the most successful and rational attempts have been those in which the destruction of the bacillus and its poison have been aimed at, especially if this has been accompanied by the use of means for promoting the rapid secretion

and excretion of the poison from the body. Here as in the specific infective diseases generally our want is an antiseptic that will help to kill bacteria, directly or indirectly, and that will not damage, but will even give healthy stimulation to the tissue cells.

In this new method of treatment it appears to be claimed that in certain periodate salts we have substances which act not only on the bacillus (as bactericides) in the alimentary canal, but also directly on the "toxines," bringing about their oxidation into less complex and more stable non-poisonous substances, which can be readily excreted by the kidneys, or may be got rid of directly from the intestinal tract. It is also claimed, but apparently with very little reason, that the periodate salts have some direct action on the nerves, this, however, is mere conjecture, and the arguments offered in support of this hypothesis are far from convincing. In the *Times* article it is stated that "there are two principal drugs employed—the crystals of periodate" (of what?) "which are powdered, and a periodate of iron." The last-named is used in such cases as demand an extra strong nerve or cardiac stimulant treatment, and where there are severe neuralgic symptoms. The first is used in several ways: first as a powder to disinfect the alimentary tract, second as a plain water solution, prepared by boiling copiously, and used as a beverage by patients to wash out the stomach in severe vomiting, which abates as soon as the walls of the stomach begin to absorb the fluid, whereby the nervous energy is stimulated, in from two minutes to an hour or two, for transfusion under the skin, and, in cases of collapse, into a vein, for restoration of the suspended circulation of the blood, third, an acid solution of the powdered crystals of much greater strength than the plain watery preparation is found to stimulate the liver and kidney and gall bladder, promoting a free secretion of bile."

It is supposed that by this treatment the body is flushed and sweetened as it were, and so far the treatment would be rational enough could it be thoroughly carried out. Far greater reliance might have been placed on the evidence put forward had the initiator of this treatment been content to place on record facts, instead of attempting to formulate a theory for everything, as his theories whilst giving evidence of his undoubted enthusiasm, indicate only too plainly that where he gets beyond the use of the test tube he is compelled to draw largely on his imagination for many of his facts and most of his explanations.

As regards the percentage of recoveries mentioned, it must be remembered that towards the end of an epidemic the fatal cases always form a much smaller proportion of the total cases than during the earlier stages of the outbreak. The people most susceptible to the attack of the disease, *i.e.* those with damaged hearts, kidneys, and lungs, have already succumbed, the weaklings have been cleared out of the way, and but the fittest and comparatively well-nourished remain. Attempts have been made to ameliorate the wretched surroundings of those most prone to take the disease, the poor are better fed and better able to withstand the ravages of the cholera organism, the "cholera fright," at first a most potent factor in the preparation of patients for cholera, has to some extent subsided, the cases are not only much less numerous, but they are of a milder type and a less fatal character. Then, too, after the first few batches of patients come in (amongst which the mortality is always extremely high) there ensues a kind of panic amongst the authorities, and the treatment consists of little more than placing the patient in a ward along with others suffering from the same disease, in order to get them away from their healthy companions; other treatment is for long of the most meagre description, and it is only when hygienic conditions have been improved, mode of transport organized, and hospital accommodation arranged that the

medical authorities have time to devote to the treatment of individual patients. As soon as patients do obtain such individual treatment and attention the percentage of fatal cases rapidly declines.

These periodates, analogous salts in the chlorates, are apparently the direct heirs to the qualities that at one time were ascribed to the chlorates, for which it was claimed that they had great power of supplying oxygen for the transformation of poisonous products in the body. It was found, however, that these chlorates when administered in large doses made their appearance in the secretions in a very slightly altered condition, not only so, but they exerted an exceedingly deleterious effect on the blood, reducing the hæmoglobin to methæmoglobin, and stopping the respiration and bringing about a fall of the blood pressure to zero. This periodate, which is apparently extremely insoluble except in acids, may be tolerated in small doses, but its physiological action, especially when administered in large doses, can scarcely yet have been studied.

As to the action on the kidneys through the nervous system, we have as yet little or no evidence that there is any direct action of the nerves on the secretion by the kidneys except through the vaso-motor system. It is usually maintained that the suppression of urine in cholera is due primarily to the extremely low general blood-pressure owing to the rapid abstraction of the fluid elements of the blood brought about by the passage of watery stools, but also in part to the irritative action on the secreting cells of the kidney of the cholera toxines, as a result of which secretion is more or less paralyzed. In order to overcome this stoppage of excretion by the kidneys, the practice of injecting warm normal saline solution has in recent epidemics been practised with some success, especially when boldly and repeatedly carried out. This treatment has the additional advantage that it not only supplies fluid to the parched tissues, but also increases the volume of blood on which the heart may contract and helps to wash away the specific poison. It is utilized to a very great extent in the new method described in the *Times*, but whether the periodates are better than common salt as a substance with which to raise the specific gravity of the warm water, yet remains to be determined. As yet the details supplied are far too meagre to allow of any definite opinion as to the value of this periodate treatment being arrived at.

It is fortunate that we have no cholera epidemic with us at present, otherwise we should have a right to complain that the *Times* has been made the medium through which what must be a very imperfect—and certainly from a physiological point of view—incorrect theory, has been presented to the public, and it will be well to await the exact accounts of those who have been entrusted with the carrying out of the treatment in the wards of the Seamen's Hospital, and the results of fuller chemical, physiological, and therapeutic experiments, minutely detailed and recorded, before we allow ourselves to be buoyed up by hopes which, previous experience has taught us to fear, may be very summarily and completely dashed. We hope that we may have no opportunity of testing the value of this new treatment in England, but there is too much reason to fear that, abroad, opportunities in abundance will be afforded during next spring and summer.

How much of the success obtained in Hamburg is to be ascribed to the factors above mentioned, and how much to the careful treatment and nursing of confident medical men, inspired by the enthusiasm of the "inventor" or promoter of the "periodates," it is difficult to say, and we shall await with interest, but with well disciplined and chastened expectation, the report of the German doctors mentioned in the *Times* on the results of their observations.

## NOTES

MR W H PREECE, F R S, has been appointed engineer-in-chief and electrician to the Post Office

A CIVIL LIST pension of £75 per annum has been granted to Mrs Dittmar, widow of Dr William Dittmar, F R S, Professor of Chemistry in Anderson's College, Glasgow, in consideration of her husband's distinguished services

THE Linnean Society, at its ordinary meeting on the 17th inst., adopted an address of congratulation to the Rev Leonard Blomefield on the completion of the seventieth year of his Fellowship of the Society, he being the father of the Society, having joined it on November 19, 1822, and being now in the ninety-third year of his age. At the time when Mr Blomefield (then Jenyns) became a Fellow of the Linnean Society, it was still under the presidency of its first President, Sir J E Smith, he was also an original Fellow of the Zoological Society, and is one of four survivors of the founders of the Entomological Society. He joined the British Association in the second year of its existence. Mr Blomefield was Mr Darwin's senior at Cambridge, was closely associated with him in his zoological researches until Mr Darwin's death, and was one of his most frequent correspondents. His early bias towards the study of nature was due to his reading White's "Natural History of Selborne" while at Eton. This was then a very scarce book. Having borrowed a copy of it from a friend, being uncertain whether he should ever see it again, he copied the whole of it in manuscript with his own hand. The address of congratulation was moved by Sir William H Flower, seconded by Mr St George Mivart, and acknowledged by the Rev Geo Henslow, a nephew of Mr Blomefield.

THE following gentlemen have been appointed to form the Fishery Board for Scotland—Mr Peter Esslemont is Chairman, the other members being Mr John Guthrie Smith, Sheriff of Aberdeen, Kincardine, and Banff, Mr George H Thoms, Sheriff of Caithness, Orkney, and Shetland, Mr Dugald M'Kechnie, Sheriff of Argyle, Mr William Boyd, solicitor, Peterhead, Mr James Johnston, fish curer, Montrose, Mr William Anderson Smith, Ledaig, Professor Mackintosh, St Andrews, and Mr J Ritchie Welch, St Andrews.

THE Royal Microscopical Society will hold a *conversazione* in the Banqueting Saloon, St James's Hall Restaurant, on Wednesday, November 30, at 8 p m.

THE annual dinner of the Institution of Electrical Engineers was held on Friday evening at the Criterion. The president, Prof W E Ayrton, F R S, was in the chair. Responding to the toast of the Learned Societies (proposed by the chairman in a humorous speech), Prof G F Fitzgerald said that learned societies were never more flourishing than they were now. The co-operation of theory and practice had been the fruitful parent of nearly all the advances of the present generation. We had such enormous stores of energy at our service that almost immeasurable prospects were open for the material improvement of man's estate. Mr Latimer Clark (past president) proposed "The Engineering Societies." He said these societies were in danger of being overlooked. They first perfected the steam-engine, then improved manufacturing implements, then the steam-boat. The engineering societies had done much more to promote the great prosperity of this country than the politicians who had so wickedly usurped the greater part of the credit. Dr W Anderson responded. The Chairman then proposed "Our Guests," with which he joined the name of Mr Mundella, President of the Board of Trade, who exercised a sort of

parental supervision over them all. No doubt sometimes there was a little disposition to grumble, as children did occasionally, at the form in which that fatherly affection displayed itself. But, whatever their feelings about the Board of Trade, there was no doubt about their feelings with respect to its president. Mr Mundella, in response, said that, whatever grievances the engineers might have against the politicians, his withers were unwrung. The Board of Trade might have given the electrical engineers some trouble if so, it was not due to him. Mr Latimer Clark had complained of the appropriation of all the credit of material progress by the politicians. Let them halve the difference. The politicians had, at all events, appointed Dr Anderson. He was speaking to a comparatively young institution, but it was to one which was growing more and more and would advance to still greater degrees of greatness. The Board of Trade owed much to the electrical engineers, who had devised systems and methods of the utmost value. He believed we were now at the outset of a great advance in the science of electric lighting. Progress would be assured when they could assure shareholders of a reasonable dividend. Two millions had already been expended in the metropolis, and we might soon hope to overtake the United States and Continental countries, which were, he feared, still to some extent in advance of ourselves. The Board of Trade had no desire to hamper the progress of electricity by needless rules, and hoped that in this, as in all other branches, science would go on its beneficent course untrammelled by any unnecessary regulations. Sir James Sivewright, Commissioner of Public Works, Cape Colony, proposed "The Institution of Electrical Engineers," to which the president briefly responded.

WE print elsewhere an abstract of a most interesting paper on stability and instability of viscous liquids, read before the Royal Society, by Mr A B Bassett. It presents in a new way the various problems involved in the calming effect of oil poured on troubled waters.

PROF J E HUMPHREY, of the Massachusetts Agricultural Experiment Station, is about to visit Jamaica for the purpose of making a study of the algæ and fungi of that island.

THE weather during the past week has, upon the whole, considerably improved, it has been mostly fine in the southern and eastern parts of the kingdom, but less settled in the west and north. Temperature has been decidedly lower, and over the central and eastern parts of England sharp frosts have been experienced. The distribution of pressure has been generally cyclonic over these islands, but over the west of Europe the anticyclonic has still held its ground. The eastern portion of England has been brought under the influence of both high and low pressure systems, being situated about mid-way between the cyclones which have skirted our western coast, and the anticyclone over western Europe. These conditions were accompanied by very quiet weather, with a good deal of local fog. On Sunday a depression, which passed along the Irish coast, caused southerly gales on that and following days in the south of Ireland and the English Channel, with very heavy rainfall in Ireland, the amount measured at Roche's Point on Monday and Tuesday mornings was nearly 2.5 inches. Towards the close of the period the European anticyclone was spreading westwards, and the barometer was high and uniform over Great Britain. For the week ended the 19th instant the official reports show that the rainfall was considerably in excess of the average over Ireland and the south of England. From the beginning of the year the deficiency in the latter district is 2.3 inches, and in the south-west of England 8.4 inches, or more than 23 per cent of the average amount. Bright sunshine was

again very deficient over the whole of England and Scotland, in the south-west of England the duration only reached about 2 per cent of the possible amount

THE *Pilot Chart* of the North Atlantic Ocean for November contains some interesting reports of the drift from some portion of the coast of the American continent to mid-ocean of a mass of forest growth resembling a floating island. It was first seen on July 28 in lat 39° 42' N, long 64° 20' W. On September 19 the *Roman Prince* reported it in lat 45° 29', long 42° 39' as "a clump of bamboos about 30 feet in diameter and 20 feet high." Between these two dates the little island drifted more than 1000 miles in an ENE direction. The month of October was very stormy in the North Atlantic, from the tracks laid down on the chart several of the storms seem to have moved along very abnormal tracks, and this fact has probably some connection with the very severe weather experienced in this country. In the early part of the month a hurricane formed in very low latitudes, and passed over Trinidad on October 6 into the Gulf of Honduras, and possibly into the Gulf of Mexico. It is unusual for a hurricane to occur in such low latitudes in the North Atlantic. Very little fog was reported, and no ice south of the 50th parallel.

SEVERAL shocks of earthquake have been felt lately in the island of Ponza. On the evening of November 16, according to a Reuter's telegram, the walls of several houses were slightly cracked by one of these shocks, which was accompanied by subterranean rumblings. No one was hurt, but alarm spread rapidly among the inhabitants, half of whom took refuge on small vessels lying along the coast, while the remainder encamped on the beach.

THE *Age Herald* of Birmingham, Alabama, gave on October 28 an account of a great meteor which had been seen on the previous day to pass over that city and disappear in a south-westerly direction. We learn from the *Mobile Daily Register* of October 29 that at Gadsden a brilliant meteor was seen at the same time, that is, between five and six o'clock on the afternoon of October 27. It passed near the zenith. Two young men employed in the *Daily Register* office at Mobile saw at the same hour in the afternoon a bright meteor in the north-west. It was about 45° above the horizon. When it neared the western horizon it exploded like a sky rocket.

A MALE gorilla (*Gorilla gina*) has lately been acquired by the Berlin Aquarium. He is larger than any gorilla that has yet been brought to Europe. He is supposed to be eight or nine years old, and was for six years in the possession of a chieftain on the Gaboon. Captain Clarke brought him to England. The *Naturwissenschaftliche Wochenschrift*—which estimates the value of this "splendid animal" as not less than 10,000 marks—says he has not yet shown any very friendly feeling for man.

It appears from a report issued by the Board of Trade that the examinations and comparisons of the Parliamentary copies of the Imperial standards show that no measurable change has taken place in the length of the Imperial standard of measure. The Imperial standard pound weight appears, however, by comparison with the Parliamentary copies of the Imperial standard pound, to have decreased in weight since it was restored and legalized by the Standards Act of 1855. The amount of diminution in the weight of the Imperial standard pound would not be appreciable in trade, and had probably arisen before the year 1872, but the Board of Trade are taking into consideration the question of restoring this standard in the manner provided by Section 6 of the Act of 1878.

THE South Australian Government has issued a full report of the proceedings of the Rust in Wheat Conference during its

third session, held in March of the present year. Among the resolutions adopted by the Conference was one to the effect that a practical system for the production and distribution of rust resisting wheats suitable to different districts should be immediately established, and that this system—subject to modifications needed by each colony—should be conducted on the following lines:—A central station for each colony for the preliminary testing of new wheats introduced into the colony, for the production of new varieties by cross fertilization and by selection, and for the distribution of suitable wheats thus obtained to representative districts of the colony, to be there subjected to a sufficient test, and, if necessary, fixed in their characters by farmers and others competent for the work, and that such wheats as pass satisfactorily this test should then be distributed to the farmers around in such a manner and by such agency as would be most suitable to the conditions of each colony. The Conference will meet at Brisbane in 1894. It is hoped that in the meantime the various colonies will publish the results of the experiments which are to be carried on during the coming year.

MR. XANTHUS SMITH, a well-known American photographer, has formed a high opinion of some of the work done in photography in England. "There is no doubt," he has lately said, "that the English photographers excel us Americans in landscape photography, and mainly for two reasons, the first being their appreciation of atmospheric effects, which is no doubt a result of their moist climate, and second, the extreme pains which they are willing to take in order to secure an effective picture." The *Photographic News* considers it "quite a comfort to record a statement like this, not because it praises English work, but because it acknowledges the pictorial effect often obtainable from a misty atmosphere." "Those who are ignorant of the subject," adds our contemporary, "invariably credit the alleged superiority of foreign photographs to the greater clearness of the atmosphere which is supposed to prevail outside the confines of Great Britain."

AN interesting case of a wild rabbit living in an almost tame condition is recorded by Helen J. Murray in the current number of *Nature Notes*, the Selborne Society's magazine. Mrs. Paul, a fisherman's wife, living in a hut between Ardnahern Farm and the mouth of Loch Gail, deserves the credit of having achieved this result. The rabbit was brought in when very young by a cat, and reared by Mrs. Paul, from whose hand it still feeds. It now spends part of its time in the woods, and part on the low sloping roof of the hut among the pigeons, or at the door among the fowls. It is shy in the presence of strangers, but quite friendly to the fisherman's wife.

It seems that since the appearance of the Russians at Tashkend a beginning has been made there in the cultivation of the better kinds of tobacco. According to the *Journal of the Constantinople Chamber of Commerce*, quoted in the Board of Trade Journal, first trials were made by a commercial firm trading between Persia and China. The satisfactory result of this cultivation, due to the favourable atmospheric conditions and to the fruitful qualities of the soil, attracted many Russian imitators, and very soon the native population followed their example, so that the area of land devoted to the cultivation of tobacco now comprises sixty-three dekalines, and it is expected that it will not stop at that point.

THE new number of *L'Anthropologie* contains an interesting article by M. Emile Cartailhac, on the Stone Age in Egypt. It is the first of a series of papers on the stone age in Africa. English readers will be glad to see that in this instalment M. Cartailhac does ample justice to some of the discoveries of Mr. Filanders Petrie, the value of whose work has also been fully

recognized lately in the German periodical *Globus*. Another good paper in *L'Anthropologie*, by M. Louis Siret, deals with the end of the Neolithic epoch in Spain.

PROF. MCINTOSH'S paper on the Scottish Fisheries, to which we referred at the time it was read at the Edinburgh meeting of the British Association, has now been issued as a pamphlet by Messrs John Leng and Co., Dundee. The paper presents a clear and interesting account of the Scottish Fisheries, chiefly in their scientific aspects, during the decade 1882-92.

THE Cartwright Lectures, 1892, delivered by Dr. Henry F. Osborn, Professor of Biology in Columbia College, have been reprinted from the *American Medical Record*. They deal with "present problems in evolution and heredity." In the first lecture Prof. Osborn discusses the contemporary evolution of man, in the second, difficulties in the heredity theory, in the third, heredity and the germ cells.

THE Kansas University has started a "Quarterly," which is to be maintained as a medium for the publication of the results of original research by members of the University. In the second number, which we have just received, Mr. E. H. S. Bailey has an interesting paper on the Great Spirit Spring Mound. The Great Spirit Spring is in Mitchell county, Kansas, on a conical limestone mound 42 feet high, and 150 feet in diameter at the top. The pool itself is a nearly circular lake about 50 feet in diameter, 35 feet deep, and the water rises to within a few inches of the top of the basin. There is a level space on all sides of the spring so wide that a carriage can be readily driven round it. Within about 200 feet of the mound is a limestone bluff, which rises perhaps 20 feet above the level of the spring. Mr. Bailey suggests that the mound may have been made by successive deposits from the spring. Although the mound is plainly stratified, this need not, he thinks, interfere with his theory, as the water may have been intermittent in its flow. The rock is very porous, and on being ground to a thin section is shown to be concretionary in structure. It is of just such a character as might have been built up by deposition from the water, as it contains the least soluble constituents of the water. The process of solidification would be assisted by the silica in the water, forming insoluble cementing silicates. An analysis given by Mr. Bailey shows that there is abundant silica in the water for this purpose.

A PAPER presenting a revision of the species of *Coryphodon*, by Charles Earle, printed originally in a Bulletin of the American Museum of Natural History (vol. iv, No. 1), has now been issued separately. The recent expedition sent out by the American Museum of Natural History to the Bad Lands of the Wahsatch formation of Wyoming was successful in procuring some valuable *Coryphodon* material. The entire collection was placed in Mr. Earle's hands for identification and study. He has been surprised by the large number of species which have been proposed, and finds upon studying and comparing the types that a great reduction in the number of species should be made.

WITH a view to determining the phylogenetic position of mammalian hair, Herr Maurer has recently been studying the sense organs of the skin, feathers, and hairs, and their mutual relations (*Morph. Jahrb.*). His researches render more evident the profound difference that exists, both in early development and in later behaviour, between mammalian hair and feathers. Morphologically, they are to be regarded as quite different organs. Are the hairs, then, *sui generis*, or may they be brought into relation with other epidermal forms? From studying the lower vertebrates, Herr Maurer considers that the skin sense organs of amphibia afford the ground on which hairs are developed. The complex relations of the root sheath of the hair

allow thus of an easy explanation. Further, as to the relation of mammalia to other vertebrate groups, as indicated by forms of integument, Herr Maurer is of opinion that mammals become separated from Sauropsida and draw closer to amphibia, thus confirming a view based on other points of organization.

FLUORSULPHONIC ACID,  $\text{SO}_3(\text{OH})\text{F}$ , has been isolated by Prof. Thorpe and Mr. Walter Kirman in the laboratory of the Royal College of Science, South Kensington, and an account of their experiments was given at the opening meeting of the Chemical Society, held last Thursday evening. When liquid hydrogen fluoride is brought into contact with sulphur trioxide a violent reaction occurs. The product of this reaction, provided any great rise of temperature is prevented by extraneous cooling, is now shown to be fluorsulphonic acid, a liquid behaving in many respects like the chlorosulphonic acid,  $\text{SO}_2(\text{OH})\text{Cl}$ , discovered by Prof. Williamson. The preparation of fluorsulphonic acid was effected in the following manner.—A quantity of sulphur trioxide was first distilled from a glass apparatus into the receiver of a distillation apparatus constructed entirely of platinum. A quantity of the anhydrous double fluoride of hydrogen and potassium,  $\text{HF.KF}$ , more than sufficient to furnish enough hydrogen fluoride to combine with all the sulphur trioxide, was then placed in the retort of the latter apparatus, and the retort connected with a long condensing tube surrounded by a freezing mixture of ice and crystallized calcium chloride. The receiver containing the sulphur trioxide was finally adjusted to the condensing tube, and was likewise surrounded by a similar freezing mixture. Upon heating the retort the double fluoride of hydrogen and potassium was dissociated, and pure hydrogen fluoride (hydrofluoric acid) distilled over into the receiver and reacted with the sulphur trioxide. The excess of hydrogen fluoride was subsequently removed by means of a current of dry carbon dioxide, the receiver and its contents being warmed to a temperature of about  $30^\circ$  during the process. The fluorsulphonic acid thus prepared is a colourless mobile liquid, which possesses an extraordinary affinity for water, reacting, in fact, with that liquid with almost explosive violence. It fumes when exposed to air, and possesses a specific mildly pungent odour quite different from that of hydrofluoric acid. It may be distilled, with but slight decomposition, in a platinum apparatus, its boiling point (corrected) being  $162^\circ.6$ . The latter constant was determined by use of a specially constructed platinum distillation apparatus, in the neck of the retort of which was fitted a small platinum tube containing a little mercury, and in which the thermometer was immersed during the process of distillation, in order to protect it from the powerfully corrosive action of the vapour. The error introduced by the use of this arrangement was very slight, and was determined by distilling liquids of known boiling points. Considerable interest is attached to the relatively high boiling point of fluorsulphonic acid, inasmuch as it is several degrees higher than that of chlorosulphonic acid, which boils at  $155^\circ.3$ . It would appear as if this fact is in some way connected with the relatively high boiling point of hydrogen fluoride itself ( $19^\circ$ ), as compared with that of hydrogen chloride, which, as most people are aware, is gaseous down to comparatively low temperatures. The main products of the decomposition which occurs to a slight extent during distillation, are most probably sulphuric acid and sulphuryl difluoride,  $\text{SO}_2\text{F}_2$ , which latter compound Prof. Thorpe and Mr. Kirman shortly hope to isolate by a method similar to that by which Behrend prepared the analogous sulphuryl dichloride,  $\text{SO}_2\text{Cl}_2$ .

THE additions to the Zoological Society's Gardens during the past week include two Maholi Galagos (*Galago maholi*) from South Africa, presented by Mr. Luscombe Searell, a Feline Genet (*Genetta felina*), a White-eared Scops Owl (*Scops leucotis*), a Tawny Eagle (*Aquila newholdei*) from Matabeleland, South

Africa, presented by Mr. B. B. Well, two Jackdaws (*Corvus monedula*, white var.) British, presented by Mr. Harding Cox, F.Z.S., eighteen Deadly Snakes (*Trigonoccephalus atrox*) from Demerara, presented by Mr. J. J. Quelch, C.M.Z.S.; a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mr. J. Pettitt, a Blue and Yellow Macaw (*Ararauna*) from South America, deposited, four Lapland Buntings (*Calcarius lapponicus*), twelve Snow Buntings (*Plectrophanes nivalis*) European, six Cirl Buntings (*Emberiza cirius*) British, purchased

### OUR ASTRONOMICAL COLUMN

THE NEW COMET.—The following observations of the "Comet Holmes" are communicated to the *Comptes rendus* by M. Bigourdan, Paris Observatory:—

Date	Paris Mean Time h m s	App. R.A. h m s	App. Decl. ° ' "
Nov 9	7 59 25	0 45 55.51	+ 38 19 25.8
9	9 28 6	0 45 53.46	+ 38 19 4.5
13	10 20 1	0 44 3.76	+ 37 53 6.2
13	10 46 32	0 44 3.17	+ 37 52 58.7
13	10 55 43	0 44 3.01	+ 37 52 57.9
13	11 10 49	0 44 2.71	+ 37 52 50.6
13	11 25 6	0 44 2.33	+ 37 52 48.6

On November 9 the comet was a large and bright nebula, perfectly round, and 5' 5" in diameter. It showed a central diffused nucleus, 10" in diameter. A rather brighter portion of an approximately elliptic form appeared to extend from the nucleus in the direction  $\rho = 127^\circ$ , its axes being 1' 5" and 30" respectively. On November 13 the comet was only seen intermittently. It was 8' in diameter and nearly round. The nucleus no longer occupied the centre, but had shifted towards the preceding portion. The elliptical region was 2' by 30", and in the direction  $\rho = 116^\circ 8'$ . To the naked eye it was easily visible, being as bright as the Andromeda nebula near it, but less easily distinguished, owing to its smaller apparent size.

The most recent elements and ephemeris have been obtained from observations made on November 9 at Karlsruhe, November 10 at Rome, and November 11 at Göttingen, and are given in *Astronomische Nachrichten*, No. 3128, from which we make the following extract:—

Elements	
T = 1892 August 15 779 M.T. Berlin	
$\omega = 300^\circ 2' 7''$	M. Aequator, 1892 0
$\Omega = 11 25 9$	
$i = 27 34 0$	
log q = 9.92222	

Ephemeris for 12h Berlin M. Time					
1892	a	$\delta$	log r	log $\Delta$	
Nov 17	oh 43 5	+ 37 32	0 2562	9 9734	
" 21	43 7	11	0 2688	0 0071	
" 25	0 44 7	+ 36 50	0 2810	0 0387	

The comet can be easily picked up with a small telescope by knowing that it lies in a line joining the stars  $\beta$  and  $\theta$  Andromedæ, about one-third of the distance from  $\beta$ .

MOTION IN THE LINE OF SIGHT.—The transformation of the great reflector of the Paris Observatory for the purpose of adapting it to the spectroscopic determination of radial velocities is described by M. H. Deslandres (*Comptes rendus* 20). Instead of having a flat mirror at  $45^\circ$ , a collimator was placed in the optic axis itself, and movable along it. The rest of the spectro-scope, which contained three flint prisms and a camera, was enclosed in a rigid steel box attached to the upper ring of the telescope. In order to control the motion, the plates forming the slit were made of polished steel and slightly inclined, so as to throw an image of the sky down into an auxiliary telescope inside the tube, which was provided with a reflecting eye-piece. Thus the observer below, standing near the great mirror, was enabled to keep the star well on the slit. With this arrangement, spectra of stars down to the 4th magnitude could be obtained, 12 cm. long, in two hours. In the blue portion a displacement of 0.005 mm. indicated a velocity of 3.6 km. per second. The lines whose displacements were measured were those of hydrogen, calcium, and iron. 250 stars are within reach of the

instrument. For  $\alpha$  Aurigæ, with a comparison of 30 lines, the velocity was +43.5 km.  $\beta$  Aurigæ is a spectroscopic double with velocities, on February 5, of -84 km. and +97 km. Venus, on April 12, had an actual velocity of 13.55 km. That indicated by the negative was 15 km.

"HIMMEL UND ERDE" FOR NOVEMBER.—The current number of *Himmel und Erde* contains many astronomical articles of interest. "The Heat in August, 1892" is the subject of an article by Prof. W. J. van Bebbber. In this he brings together all the statistics of the temperature readings during the interval between August 11 and 25, and shows by weather charts the general state of the weather, such as wind, barometer, &c. The following few values, showing the highest temperatures recorded and extracted from the table mentioned above, may be of interest:—

Place	Aug	Temp Fahr	Place	Aug	Temp Fahr
London	23	80.6	Cassel	17	96.8
Oxford	23	77.0	Grunberg	19	102.2
York	23	73.4	Karlsruhe	17	96.8
St. Petersburg	26	86.0	Bamberg	18	100.4
Stockholm	26	82.4	Constantinople	21	100.4
Paris	18	95.0	Madrid	16	107.6
Biarritz	16	107.6	"	17	107.6
"	17	104.0	Rome	17-21	93.2
Brussel	18	95.0	Lagouat	23	105.8

Dr. J. Scheiner, on "Astronomy of the Invisible," deals with the discovery of the dark companions of Sirius and Procyon. He commences with an historical sketch of the study of the proper motions of the fixed stars and leads up to the most modern observations describing the results obtained with regard to Sirius and Procyon. Prof. Barnard, with the help of two excellent woodcuts, explains the working of the great Lick refractor. To prepare the instrument for micrometric work, he says five minutes is required, but for photographic work ten minutes is necessary, as a photographic correcting lens has to be adjusted to compensate for the difference between the photographic and optical focus, the large spectroscope absorbs nearly half an hour's work before it is ready for observation.

OBSERVATIONS OF PERSEIDS.—During the August display of the Perseids it has been noticed that in addition to the principal radiant point several minor ones have been observed, which although not very far distant from the primary one, are still far enough to suggest that they belong to another swarm of particles following a different track in space. The orbit, which the particles in the main follow, corresponds, as is well known, to that of the comet of 1862 III, and M. Bredikhine has suggested that the particles producing these minor radiant points belong really to the same swarm, only have either been acted on by external forces such as the perturbations of the major planets, or have been projected from the comet itself at different periods.

With the intention of bringing some facts to bear upon this idea, M. Puisseux, in the *Bulletin Astronomique* for October, gives the results of his observations made in August of last year, which seem to confirm those of M. Bredikhine in several points of view.

His method of observation was simply to chart down on a large celestial globe the positions of the trails as observed. A glance at this globe, after 199 positions had been so recorded, indicated that the area of radiation occupied a considerable surface, and extended principally in the directions of right ascensions, that several distinct centres of concentration were observable, and that the same radiant points, in general, manifested their activity at the same time, i.e., on the evenings of August 10, 11, and 12, and some on August 7. In the table accompanying this paper M. Puisseux shows that no less than fourteen different centres of radiation were observed. Table II, which we produce here, contains the essence of the whole work, and shows the positions of the radiant points in question, together with the corresponding elements of the orbits deduced. It must be remembered of course that their values cannot be very accurate, owing to the difficulty of observation, but the results are nevertheless interesting. The different radiant points are denoted by A, B, C, &c., while  $\alpha$  and  $\delta$  represent

their right ascension and declinations, the other nomenclature is that usually adopted in cometary computations

	$\alpha$	$\delta$	$\lambda$	$b$	$\Omega$	$i$	$q$	$\omega$
A	44° 5'	49° 1'	57° 1'	30° 7'	138° 6'	127° 3'	0.9643	296° 2'

### GEOGRAPHICAL NOTES

THE Royal Geographical Society has determined on a change in the form and alteration in the title of its *Proceedings*, which will materially enhance the value of the monthly publication. The size of each part will be increased to ninety six pages, and two volumes will be published in the year instead of one as formerly. Internally the arrangement will be slightly altered, and while the strictly geographical character of the publication will be maintained, the notes and record of geographical work from other countries will be made at once more systematic and more popular. A special feature will be the record of the "Geographical Literature" of the month, summarizing all the accessions to the library, both books and memoirs. This will form a subject-index to geographical literature, and serve as a continuous appendix to the exhaustive subject catalogue of the Society's library which is now being compiled. The editorship of the new series remains in the hands of Mr J. Scott Keltie, the assistant secretary.

WITH reference to the note on the death of Lieutenant Schwatka, the Alaskan explorer, published last week, we are glad to observe that an official enquiry negatived the theory of suicide, and showed that the fatal result followed from an overdose of morphia taken medicinally.

THE German colonial authorities have recently come to a very important decision as to the official spelling of the place names of their various protectorates in Africa and New Guinea. European names are to retain their ordinary form, but all native names are to be rendered phonetically according to a new set of rules. These rules so closely resemble those put forward by the Royal Geographical Society, and now widely used, that it appears possible by some slight concessions on both sides to make one set serve both for English and German. The letters *c*, *g*, *z*, and *s* are dispensed with as redundant, *c* and *a* being rendered by *ts*, *x* by *ts*, and *g* by *kw*. The guttural *ch* becomes *kh*, the English *ch* being given as *tsch*, and the sound of the English *y* as *dy*. The German *y* sound will be represented by *y*, and the letter *j* used only for the French sound, which is represented in English as *zh*. The German sound of *w* is rendered as *v*, the letter *w* being kept for the English sound. Unfortunately the letter *s* is kept for its soft German sound, the sharp sound of the English letter being shown by *z*. The use of the English *z* would have overcome this difficulty, and removed the most serious obstacle to a common orthography.

CAPTAIN MONTEIL, whose arrival at Kano on his way to Lake Chad was referred to in May last (vol. xli. p. 110), has at last been heard of, and his mission, although involving two years of travel in the Sudan and Sahara, appears to be successfully completed. The facts could not be put more concisely than in Monteil's official telegram to the French Foreign Office, which arrived on November 15—"October 17. To-day I entered the territory of Fezzan by way of Tejerri coming from Kuka. Having set out from Kano on February 19, I reached Kuka on April 10, where the reception was excellent. I left Kuka on August 15 with a guide, sent by the Sheikh to accompany me to Murzuk, which I expect to reach on or about the 25th, and to stay there just long enough to arrange my departure for Tripoli. Badaire has borne the

journey exceedingly well. My men are all with me, except two left at Kuka." This is the most important journey through the Central Sudan and Sahara since the classical explorations of Barth and Rohlfs.

### STROMBOLI IN 1891<sup>1</sup>

STROMBOLI is one of the most noted but least studied of volcanoes. The regularity of the weak explosions which, succeeding each other at intervals of a few minutes, characterize its normal state, gives rise to the idea that its action is always thus uniform and monotonous, and the occasional paroxysms to which it is subject are apt to be overlooked. In reality the so-called Strombolian phase of volcanic activity differs from the Plinian phase exhibited by Vesuvius and certain other volcanoes merely by the absence of intervals of perfect repose between the violent outbursts which are characteristic of the latter type. It is in this difference that the explanation of the fact is to be found, that from time immemorial no explosion in any way comparable to the great explosions of Vesuvius have occurred at Stromboli, for the ceaseless activity of the latter prevents the accumulation of sufficient force to produce a powerful and destructive effect. But from time to time the throat of the volcano does get more or less choked, and the efforts of the imprisoned vapour to escape result in an eruptive phase of some violence. Such an event took place during the latter months of last year, and the following description of the phenomena is based on the observations of Profs. Ricco and Mercalli, and of Ing. Arcidiacono.

The state of the volcano preceding this outburst had been one of relative calm for two years. In October, 1888, an explosion had opened three new mouths on the upper edge of the Sciara del Fuoco, from one of which lava was emitted. This was the commencement of a period of increased activity, with repeated issue of lava, lasting nine months till June, 1889. From this date to the eruption of last year, and particularly during the six months just preceding, the activity was less than normal. It is to be noticed, however, that there were two short intervals of recrudescence, lasting only a few days, at the end of December, 1890, and January, 1891.

On June 24, 1891, at 12.45 p.m., two strong earthquake shocks were felt over the whole island at an interval of a few seconds. Loud rumblings and a violent explosion followed each. The shocks were not confined to the island of Stromboli, but were felt at Salina, a distance of 40 kilometres. Even the subterranean rumblings were heard at the latter island. The first shock and the first explosion were, as might be expected, more violent than any which succeeded. Windows were broken at the semaphore station, and a great precipice of rock fell into the sea at the Filo del Cane, and other rocks in the same locality were so loosened that they fell on following days. Two powerful columns of ash, like thick smoke, arose from the crater and ascended far above the summit of the island. Great masses of scoria were ejected and fell toward the northern part of the island, burning the grass and fig trees. A boat passing to the north-east of the island at the time of the first explosion could not see the semaphore signals, owing to the quantity of ash in the atmosphere. Lapilli fell around the eruptive mouths for a radius of a kilometre and a half, and a fine, dark grey ash rained over the whole island. A stream of lava issued from a point on the Sciara del Fuoco near to the most western mouth, and a deep fissure formed its upper rim nearly in the same place as that of November, 1882. For two days the lava continued to flow, and loud explosions were frequent. The rumblings were almost continuous. On the 26th the emission of ash ceased, but moderately vigorous outbursts occurred with the ejection of incandescent scoria till the 27th, but on the 28th and 29th the volcano had resumed its wonted calm. On the 30th, however, a fresh earthquake, accompanied by rumblings and a violent explosion, showed that the volcanic forces were not yet spent. An immense column of vapour and incandescent materials arose from a new breach on the edge of the Sciara, while an abundant current of lava flowed down the slope reaching the sea at its foot. The whole of the powerful explosions on the 30th were repeated at short intervals, but the activity

<sup>1</sup> Sopra il Periodo eruttivo dello Stromboli cominciato il 24 giugno, 1891. Relazione del Prof. A. Ricco e G. Mercalli col Appendice dell'Ingegnere Arcidiacono. ("Annali dell'Ufficio Centrale Meteorologico e Geodinamico.") XI Pl. 3, 1892.

gradually declined till July 4, when its normal state was reached. The eruptions were again violent, with emission of lava from the 16th to the 23rd of July.

The mouths on the edge of the Sciara, which were contemporaneously active during the above period, were four in number—two at the northern end and two at the western end. One of the former pair was opened by the explosion of June 30, and from it was ejected the greater part of the detrital material of the eruption, so that around it a cone has been built up, truncated by a crater, sub-elliptic in form, of about 60 metres in maximum diameter. The height of this new cone above the old edge of the Sciara is about 50 metres. The other crater is situated on the deep fissure mentioned above, and at night, from the sea the incandescent lava could be seen in free communication with the atmosphere—a circumstance which explains the fact that the explosions from this crater were rare and of feeble intensity. The two western ones were situated one below the other with an interval of about 30 metres. Near the lowest, three large fumaroles gave forth dense columns of steam, while other lesser fumaroles were plentifully scattered about. The majority of the explosions took place from these two mouths. During this same period, lava was emitted three times, (1) on June 24, soon after the first two explosions from the most western part of the Sciara, (2) on June 30, from the crater on the fissure, (3) on July 16, from the central part of the Sciara, between the first two. They all reached the sea, and since the second stream doubled itself round an obstacle about half way in its course, four new points were formed on the shore. The thickness of the lava at these points varied from 4 to 6 metres. Specimens of the lava collected from the most western stream showed that it consisted of an almost homogeneous blackish brown paste, compact in the interior, but becoming more and more porous and reddish in colour towards the exterior. Some of the larger cavities were internally covered with a shining brown patina. Externally it was covered with a rough crust, reddish-brown in colour, and of scoriaceous aspect. It was sensibly attracted by the magnet, and melted without effervescence to a brownish-green glass. Crystals of plagioclase, augite and olivine were apparent. In section, about two-thirds was rendered opaque and black by very minute microlitic granules of magnetite which were intimately mixed with a transparent glassy base, colourless or inclining to greenish. The remaining third consisted of a great number of colourless transparent microlites of plagioclase. Fluidal structure was only just apparent. In this microlitic paste were scattered crystals of plagioclase, augite, and olivine. The augites were greenish in section and possessed a feeble pleochroism. The olivines were corroded and irregularly fractured.

Analysis gave the following numbers —

	Stromboli	Etna Mean of analyses of 20 modern lavas
Silica	50.71	49.45
Alumina	13.99	19.30
Ferric oxide	5.13	11.82
Ferrous oxide	9.10	—
Manganese oxide	4.2	—
Lime	10.81	10.21
Magnesia	4.06	3.69
Potash	3.02	1.33
Soda	2.87	3.58
Loss on ignition	24	—
Cl and SO <sub>2</sub>	(traces)	—
	100.35	99.38

The lava is similar to other lavas of Stromboli, and to show the great similarity between the lavas of Stromboli and Etna, the mean of the numbers of twenty analyses of modern Etna lavas is appended for comparison.

The scoria, lapilli, and ash of the eruption present no special features, but are what might be expected from a lava of the above composition.

Although the volcano had reached a state of comparative calm at the end of July, this did not last for very long. Towards the end of August fresh signs of activity gave warning of an approaching explosion, which took place on August 31. It was preceded by an earthquake a few seconds before, and as a result a vast column of ash rose above the volcano, while scoria and other projectiles were shot out to a considerable distance. Soon after, a fine ash, dark red in colour (instead of black as in

June-July), fell over the island, covering the ground in some places to a depth of several centimetres. On the evening of September 1 dense columns of ash were again emitted, and in the afternoon of September 3 the whole crater was enveloped in a thick mantle of steam, in the midst of which could be dimly seen a reddish-grey column of ash rising with extraordinary violence to a great height, when it spread out into a volcanic "pine." A fresh stream of lava was also observed. Eruptions succeeded each other at short intervals, accompanied by continuous rumblings, interrupted now and again by loud explosions, like heavy artillery. As far as could be observed, on the western side of the crater was a single mouth of almost circular form, 10 metres in diameter, which was most active in sending up vast columns of ash and projectiles of all kinds. To the east could be seen one or more little mouths, which tranquilly emitted large volumes of steam, while in the midst a large aperture, 30 metres in diameter, irregular in form and deeply fissured, was in powerful action. The activity, however, gradually quieted down, and towards the end of the year the volcano resumed its normal state.

In conclusion, it is useful to compare this eruptive phase of Stromboli with other contemporaneous seismo-volcanic phenomena of the Italian peninsula. It appears that earthquakes occurred in various districts in the early months of 1891, especially one on June 7 in the Verona district, rather severe, occasioning loss of life. Vesuvius was rather more active than usual during the whole of June, and in correspondence with this the great fumarole of the solfatara at Pozzuoli, increased in temperature. It is particularly interesting to note that Vulcano, the other active volcano of the Lipari Islands, remained in perfect calm during the whole period, emitting only vapour from the fumaroles. As, however, the character of the eruptions and the lithological composition of the material ejected from this volcano differ so greatly from those of Stromboli, it is tolerably certain that there is no free and direct communication between the reservoirs of these two volcanoes. In fact, Stromboli presents a much greater analogy with Etna. The similarity of the lithological composition of the lavas of these two volcanoes has already been referred to, and, further, Prof. Mercalli observes that the last four or five eruptions of Etna have all been immediately preceded or followed by a paroxysm at Stromboli. It is thus possible that there is a real relation between them.

L. W. FULCHER

### A LARGE METEORITE FROM WESTERN AUSTRALIA.

IN the *Mineralogical Magazine and Journal of the Mineralogical Society* of July, 1887 (vol. vii) Mr. L. Fletcher, M.A., F.R.S., president of the Society, describes four specimens of a new meteoric iron found at Youndegin in Western Australia. They were discovered about three quarters of a mile to the north west from the top of Penkarring Rock, in the above district, about seventy miles from York. These fragments were found by Alfred Eaton, a mounted police constable, when on duty in the district of Youndegin, when he brought in one of the four pieces he found on January 5, 1884. Mr. Fletcher states that the late Mr. Edward F. Hardman, F.G.S., the then Government geologist, expressed his belief in the meteoric origin of these iron masses. Later the above-named Alfred Eaton was sent with a native assistant with instructions to bring in the other three pieces, and at the same time an unsuccessful search was made for additional fragments. In the above account it is stated that the four pieces were lying loose on the surface, three of them close together, and the fourth fifteen feet away. They weighed respectively 25½ lbs., 24 lbs., 17½ lbs., and 6 lbs., the largest and smallest fragments are now in the British Museum collection, and the specimen of 24 lbs. is in the Geological Museum at Freemantle, and the fourth piece, weighing 17½ lbs., was presented to the Melbourne Museum in Victoria.

The new specimen now in my possession was discovered last year, and weighs 382½ lbs., and measures 22½ inches high, 20½ inches wide, and 13½ inches in its greatest thickness. In form it is roughly convex on one side and concave on the other, on both sides of which are large depressions or pittings similar to those usually observed on other large masses of meteoric iron. It is somewhat triangular in outline, but with irregular sides. It has one small hole quite through the mass near the top, and numerous deep holes, one near the bottom left hand corner

having a diameter of about  $1\frac{1}{2}$  inches and 4 inches deep, another at the opposite bottom corner 2 inches deep and 2 inches in diameter, also another of 3 inches deep, and several others. On the upper edge especially, and at several other parts near, also on the edges, are fractured surfaces, as if in its fall a mass or masses were broken off, leaving a coarse crystalline structure, and which would indicate that several other large holes having existed before its fall on the earth, probably all or most of the pieces were connected together, and might have fallen in one mass. It would be interesting to know if any of the pieces fitted together at the fractured surfaces as seems to me might be

detach a fragment of which the cut face was not  $2\frac{1}{2}$  inches square.

Mr. Fletcher also states that on treating a specimen of this Youndegin iron to the action of bromine water, or of dilute nitric acid, the polished section gave no definite figures, but assumed a damascened appearance very like the Lucuman iron and of that of Brazos, being very similar to the latter in the proportion and distribution of the Schreibersite, some specimens of the Arva, the Sarepta, and the recently found Canon Diablo are similar as exhibiting these characters.

One fifth natural size

possible. I observe that the two specimens of this iron in the British Museum collection exhibit similar fractures on the edges. Before receiving this specimen I was informed that two masses were found, but have no information at present as to the size and weight of the other.

Mr. Fletcher in his paper minutely describes the size and form of the two British Museum specimens, and that the specific quantity was determined from three small pieces from the larger specimen, and gave 7.86, 7.85, and 7.72. He also states that a portion was cut off the larger piece by means of hack-saws, and was found to be so hard that three weeks were required to

The Youndegin iron was also remarkable in containing the minute cubic and modified cubic crystals, having metallic lustre and of a greyish black colour, and which were determined to be graphitic in character, but of a diamond-like form, but were later found to be still distinct from the diamond, but having somewhat more the features of graphite. Mr. Fletcher therefore decided to give the name of Cliftonite to this substance, as being a new form of a carbon mineral. A most exhaustive description of this new mineral is given in his paper. Similar crystals of this substance are found in one or two other meteoric irons.

The composition of the Youndegin iron was found to be as follows —

Iron	92 67
Nickel	6 46
Cobalt	0 55
Copper	trace
Magnesium	0 42
Phosphorus	0 24
Sulphur	none
Insoluble cubes	0 04

100 38

JAMES R GREGORY

### THE CROSS-STRIPING OF MUSCLE

PROF RICHARD EWALD of Straasburg, has just communicated a paper to the fifty second volume of the *Archiv f. d. ges. Physiol.*, in which he confirms Prof Haycraft's views concerning the structure of striped muscle. The latter observer has held for many years that muscle fibrils are varicose (threads), and that the cross striping is but an optical appearance due to this varicosity. The varicosity is often difficult to demonstrate in the ordinary way, and most histologists were not prepared to admit that the stripings are all and entirely due to it. Prof Haycraft, however, recently brought forward to the Royal Society of London, and to the Berlin International Medical Congress, fresh and striking proof of the strength of his position, by demonstrating films of moist collodion, on which pieces of muscle had been pressed and then withdrawn. As a result of this pressure the collodion films were stamped as with a seal, and the impressions revealed in striking detail every stripe of the original fibre. Prof Ewald confirms these experiments in the fullest manner, but suggests that the collodion impressions might be produced on the assumption that there are layers of hard and soft material alternating with each other in the course of the fibrils. In this case the hard material would press into the collodion and make a series of furrows, which would appear as a series of stripes when examined with the microscope. Prof Haycraft had previously demonstrated the varicosity of the fibrils, seen by transmitted light, and had published photographs of his preparations, but Prof Ewald was still sceptical upon this particular point, and sought to assure himself still more conclusively. With this end in view he examined muscle, which had been rendered quite opaque, by means of reflected light, for under these circumstances the influence of the internal structure would be entirely set on one side, and the surface of the fibrils would alone receive and reflect the illuminating rays. For purposes of illumination Prof. Ewald used the apparatus of W and H Seibert, of Wetzlar, by means of which vertical rays can be projected upon an opaque object; and he rendered his preparations, both of fresh and of hardened muscle, quite opaque by a method of over-silvering. Under these conditions Prof. Ewald found that the cross-striping is most distinct, and he was able, with his admirable method of illumination, to examine the surface of a muscle just as one may observe the surface of the country at night by means of a search light from an observatory. With the light perfectly vertical the tops of the ridges of the muscle are bright, and the valleys on either side in half-light. By shifting the light to one side or to another the slopes of the ridges can be thrown alternately into shadow or bright light. Prof. Ewald concludes by admitting that his experiments fully prove that the striping is due to the shape of the fibrils alone, and that the internal structure of the muscle plays no part in its production.

### IRIDESCENT COLOURS<sup>1</sup>

ON taking a general survey of coloured objects, whether natural or artificial, we become aware of the fact that whilst the colours of some remain unchanged as regards tint, whatever their position in relation to the incident light, the tint of others varies with every alteration in their relationship to such light source. We thus see that so far as their colours

are concerned all bodies may be arranged in two groups<sup>2</sup> according as their colours change or do not change in tint as their angular relationship to the light varies. Nor is this classification entirely an artificial one, since, as will shortly be seen, though this change in tint with variation in the light source is an essential difference, it is not the only difference, even in the colour manifestations of the two groups, for it is also characteristic of the nature of the colour producing structure. It is to the above mentioned varying colours that we apply the term iridescent, from the resemblance they have in the sequence or play of colours to the tints of the rainbow. The unvarying group of colours, having no equivalent term to "iridescence" to express the nature of their colour production, are spoken of as "pigmentary," or absorption colours. In naming examples of objects, natural and artificial, grouped as above in accordance with the nature of their colours, it is difficult to make a selection where all are so varied and characteristic. I have preferred therefore to cite only such instances as I myself possess, and am therefore able to show you. As examples of pigmentary colours, I need only name one or two for the sake of comparison, since the colours of most objects ordinarily met with are pigmentary. Leaves, flowers, dyes, birds, fish, insects, minerals, &c., exhibit these colours, some almost entirely, and all, excepting fish, in far the majority of instances. Of objects displaying iridescent colours we have also examples in the various divisions of the animal, vegetable, and mineral kingdoms. Amongst birds the most striking examples are found amongst the humming birds, sun birds, birds of paradise, &c. Insects, again, furnish numerous examples, more especially amongst tropical species, though not, perhaps proportionally in greater numbers than amongst those belonging to our own more temperate regions. The colours of fish are almost entirely iridescent, since their very whiteness, or silvery sheen, is due to the admixture of the iridescent colours of innumerable minute thin lamellæ, too small to be seen individually with the naked eye, but plainly perceptible under the microscope. In the vegetable kingdom iridescent colours are far more numerous than is ordinarily recognized, since the surfaces of the cell walls produce interference colours which are more or less obscured by the pigmentary colours of leaves and coloured flowers, but may be readily seen in the case of white flowers by the aid of a lens and sunlight. Under these conditions each cell may be seen to sparkle with its own iridescent colour, forming, by admixture of the interference tints of neighbouring cells, the varying shades of white seen in numerous flowers which are devoid of pigmentary colour. Mineral bodies displaying iridescent colours are also numerous, opals, sunstone, fire marble, felspar, mica films, tarnish on various metallic crystals, certain crystals of chlorate of potash, &c., are examples.

In describing the various natural objects for purposes of identification, or mere description, no account can be considered complete which omits all reference to their colours, and more especially is this the case where the colours constitute such a striking feature, as in the case of iridescent bodies. In innumerable instances, more especially amongst birds and insects, their specific names are taken from some conspicuous colour they possess. It thus becomes evident that a correct description of the colours of bodies is of importance, and where these colours are of the pigmentary, or unchanging kind, this is a matter of no difficulty. How different, however, in the case of objects, the colours of which not only vary with every change of position, but disappear altogether, unless viewed with special relation to the light source. Nor can it be wondered at that descriptions of these objects, even by observers of undoubted repute, vary according to the different angles from which they have been viewed, or are vague and profuse, owing to fruitless attempts to describe their changing tints produced by every movement. The fact is, no words can convey an adequate impression of the gorgeous effects produced by most of such objects, whether birds, insects, or fish, when in motion in brilliant sunshine. Some notion of the difficulties to contend with in describing the colours of humming birds, for example, may be gathered from the remarks of Wallace in his work on "Tropical Nature," when speaking of humming birds:—"In some species they must be looked at from above, in others from below, in some from the front, in others from behind, in order to catch the full glow of the metallic lustre, hence, when the birds are seen in their native haunts, the colours come and go and change with their motion, so as to produce a startling and

<sup>1</sup> By Alex. Hodgkinson, M.B., B.Sc. Reprinted from the fifth volume of the fourth series of "Memoirs and Proceedings of the Manchester Literary and Philosophical Society" Session 1891-92.

beautiful effect." Most observers, in describing the colours of iridescent bodies, do so by attempting to depict the varied effects produced by casually changing the position of the object in relation to the light, omitting to mention the exact sequence of the play of colours, or the relation of these colours to the direction of the iridescent light, *i.e.*, whether produced by perpendicular or oblique illumination. Here is a description of the tufted neck humming bird, *Trochilus ornatus*, taken haphazard from a well known work—"The throat is of a fine green colour, variable in different lights to a golden hue with a yellow or brown metallic lustre, and below that the whole of the belly is a rich brown, glossed with green, and golden." Such descriptions as the above, which happen to be the first I met with in seeking for an instance, are vague, and fail to give a definite idea of the appearance of the object. But vagueness in the description of these objects is not the only result of the changing character of their colours. As might be expected, where such variation in appearance exists, the descriptions of different authors are almost as variable as the colours. Few attempt descriptions without acknowledging the hopelessness of the task. Thus Jardine, after describing this humming bird, *Chrysolampus mosquitus*, remarks—"It is impossible to convey by words the idea of these tints, and having mentioned those substances to which they approach nearest, imagination must be left to conceive the rest." And I adduce this quotation as fairly expressing the feeling of naturalists in reference to the description of iridescent objects generally. Recognizing the admitted inability of observers to convey by description an idea of the appearance of these iridescent objects, and having myself, for many years, constantly experienced the same difficulty, I have been led to adopt a method for the examination of such objects, which, whilst extremely simple and available in its application, yields unvarying results with different observers, results, moreover, which admit of the simplest description.

Before describing this method, I may say that long experience in the examination of iridescent objects has proved to me that, almost without exception, the colours of natural iridescent objects are due to interference produced by thin plates. In order, therefore, to render clear the principles on which the method I propose is founded, I will briefly refer to certain fundamental facts in connection with colour production by thin plates, and for this purpose will select a thin film of mica, which with light at perpendicular incidence, appears red, iridescent red. If, now, this plate be inclined so that the light falls on it at a more oblique angle, it is, of course, reflected at the same angle, and now appears orange, and if the plate be still further inclined, the reflected light appears yellow, then yellowish green, green, and bluish green, and if the light were not too copiously reflected from the first surface to allow of perceptible interference by further inclination of the plate, all the colours of the spectrum in their proper sequence might be observed. The same results, but much more vividly, may be seen in these crystals of chlorate of potash. Thus, we see that by rendering the incident light more and more oblique, the reflected light changes from a lower to a higher tint, that is, from the red towards the violet end of the spectrum. And this is what occurs in the case of all iridescent bodies, as the incident light becomes more oblique the colour changes to the tint above it in the spectral order, so that, if we know what colour any such object appears when seen at a certain angle, we can infer what colour it will change to on varying the incidence. This beetle (*Sagra purpurea*), for instance, is red at perpendicular incidence, it will, therefore, appear orange yellow and green when examined by successively increased obliquity of light. And the same is true of all other iridescent red objects. If the object at perpendicular incidence be green, as in the case of this beetle (*Buprestis*), it will become blue and then violet as the incidence is increased. We thus see that an iridescent object varies in colour, simply because it is examined by light incident, and therefore reflected, at different angles. Thus, different observers see the same iridescent object of a different colour, when they view it illuminated by light at a different angle of incidence. If, however, the object is seen by all at the same angle of the incident light it will present the same colour, and this is, in fact, what the method I propose ensures, *i.e.*, that iridescent objects shall always be seen by light at one and the same angle of incidence. The angle I select is one of 90, so that the incidence and reflection are normal or perpendicular to the reflecting surface. By selecting this angle all

trouble of measuring angles is avoided, since we know that the incidence is perpendicular when it coincides with reflection. Now, the reflected light may be made to coincide with the incident light by reflecting it on to the object by means of a mirror, and so adjusting the object that the light reflected from it passes to the eye through a perforation in the mirror. When examined in this way iridescent objects are marvelously altered in appearance, their changing colours are replaced by one fixed tint, visible only in one position, a fact which serves at once to distinguish them from bodies coloured by absorption, which remain coloured whatever the relation to the incident light. Such methods of examining bodies scarcely takes more time than by the eye alone. The mirror may be attached to a spectacle frame so as to leave both hands free, such as the one I show, or may be a simple hand mirror. For objects too small to be seen by the unaided eye, I have so arranged the microscope that light is made to pass down the tube of the instrument, through the object glass on to the objects, and by a special arrangement, so adjusted the position of the object that the light is reflected back again through the instrument to the eye. The method is thus available for macroscopic as well as microscopic objects.

To illustrate the practical value of this plan of examination, I have here a few objects exhibiting iridescent colours, which, by trial, will be found to give the following results—

The crest of this humming bird, *Chrysolampus mosquitus*, which, to the unaided eye, appears resplendent with all shades of red, orange, yellow, or green, according to the angle of the incident light, appears, when examined by the mirror, of one unvarying red tint, disappearing when the object is moved but absolutely unchanging in tint. Such an object, therefore, I should describe as "iridescent red", all else regarding its colour may be inferred. Again, the breast, or gorget, of the same bird reflects all shades of orange, yellow, or green to the eye alone, with the mirror it is seen of a deep orange, which, as before, is unchanged in tints by any variation in position. Such an object I would describe as "iridescent orange." The gorget of another humming bird, *Calliphlox amethystina*, to the eye alone appears crimson, orange, yellow, or green with the mirror it is iridescent crimson only, spectroscopically a red of the 2nd order. Amongst insects, instances of iridescent species are numberless, the results of examination are just the same as in other iridescent bodies. This butterfly, *Morpho*, to the eye alone appears either greenish blue, blue, or violet, as its inclination to the light varies, examined with the mirror it appears green, and should be described as iridescent green, or iridescent bluish-green. This beetle, *Foroplcura bacca*, appears any shade of red, yellow, or green to the eye alone, with the mirror only iridescent red. In this extraordinary beetle, *Chrysocroa fulminans*, we have all the colours of the spectrum in their natural sequence, beginning with red at the tip of the wing case, and ending with violet higher up the elytron. These colours vary in an indescribable manner when attentively examined at different angles of incident light with the eye alone, with the mirror the wing cases are seen to be coloured successively from base to tip iridescent green, yellow, orange, and red, and these tints remain unaltered by change of position of the object. This piece of *Halotis* shell exhibits indescribable changes of colour with every movement, but the difficulty of description, though by no means removed, is immeasurably lessened by the use of the mirror. And the same with this specimen of iridescent iron ore, its colours, which vary to the unaided eye, remain unchanged when examined by the mirror. To simplify the description of iridescent objects, therefore, I would advocate the above method, and would describe the result of such examination by recording the colour observed by aid of the mirror, and prefixing the term "iridescent" to express the changing properties of the colour. Bearing in mind the unvarying nature of these changes, a far clearer idea may be formed of the appearance of these objects than from any attempted description of what is admittedly indescribable. Time and space are also economized by the omission of lengthy descriptions. The accuracy, and, therefore, the value of any description of colour, is always enhanced by mapping its spectrum, more especially is this true in the case of iridescent colours. This is easily done, and by applying such map to a spectral chart, the order of the colour, and therefore its tint, is apparent. In examining many objects, chiefly birds or insects, by means of the mirror as above described, apparent exceptions are repeatedly met with to the fact stated above, that the colour

is invariable in tint and disappears by inclination of the body. Such instances are no real exceptions, but are due to the reflecting plates being curved, or having pigmentary matter beneath them, or an opalescent medium above them. In this way some of the most extraordinary and beautiful colour effects it seems possible to conceive are produced.

In examining objects with the perforated mirror a single light is necessary. The sun is of course the best, and the electric light probably almost as good. I frequently employ the lime-light, but a good paraffin lamp may be used as a substitute. Ordinary gas is unsuitable. The light should be placed in front of the observer, its direct rays being prevented from falling on the objects by means of a book or partition of some kind resting on the table, and of such a height that the light can be seen above it. On placing the mirror to the eye the light may be reflected from the mirror on to the object, and the latter manipulated so as to reflect the ray back through the perforation in the mirror to the eye. The incidence is thus known to be normal, and the colour observed is the one to be recorded.

### UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The following letter has been addressed by the University of Cambridge to that of Padua, which is about to celebrate the tercentenary of Galileo's professorship—

*Universitas Cantabrigiensis Universitati Patavinae S P D*

Litteras vestras, viri doctissimi, GALILEI GALILEI Professoris vestri celeberrimi in laudem conscriptas vixdum nuper perlegeramus, cum statim in mentes nostras rediit non una Italiae regio viri tanti cum memoria in perpetuum consociata. Etenim nostro quoque e numero nonnulli urbem eius natalem plus quam semel invisimus, ubi Pisano in templo lucernam pensilem temporis intervallis aequis ultro citroque moveri adhuc juvenis animadvertit, etiam Vallombrosae memora pererravimus, ubi antea scholarum in umbra litteris antiqui animi puerilem imbuerat, ipsa in Roma ecclesiam illam Florentinam intravimus, ubi doctrinae auae de telluris motu veritatem fato iniquo abiurare est coactus, Florentiae denique clivos suburbanos praeterivimus, ubi propecta aetate caeli nocturni sidera solus contemplantur, ubi extrema in senectute diei lumine orbatum cum MILITONO nostro collocutus est, ubi eodem demum in anno mortalitatem explevit, quo NEWTONUS noster lucem diei primum suscepit.

Hodie vero ante omnia non sine singulari voluptate sedem quandam doctrinae insignem, intra colles Euganeos urbemque olim maris dominam potius recordamur, ubi trecentos abhinc annos saepe, qui ARCHIMIDES discipulorum ex omni Europae parte confluxum numero ingenti erudiendo vitam suam maturam maximam cum laude dedicavit, ubi, ut LIVII vestri verbis paulum mutatis utamur, ultra colles camposque et flumen et assuetam oculis vestris regionem late prospiciens, caelo in eodem, sub quo vosmet ipsi nati estis et educati, instrumento novo adhibito inter rerum naturae miracula primus omnium Lunae faciem accuratius exploravit, Iovis satellites quatuor primus detexit, Saturni speciem tergerminam primus observavit, utraque mundi orbem ingentem a Saturno lustratum fore suspicatus est ut etiam alii planetae aliquando invenirentur.

Ergo vatis tam verach, auguris tam providi in honorem, nos certe, qui Professorum nostrorum in ordine planetae etiam Saturno magis remoti ex inventibus alterum non sine superbia nuper numerabamus, hodie alterum ex Astronomiae Professoribus nostris, GEORGIUM DARWIN, nominis magni heredem, nostrum omnium legatum, quasi Nuntium nostrum Sidereum, ad vosmet ipsos libenter mittimus. Vobis autem omnibus Idcirco gratulamur quod tam Italiae totius, tum vestrae praesentis tutelae tradita est viri tanti gloria, qui divino quodam ingenio praeditus rerum naturae in provincia non una ultra terminos prius notos scientiae humanae imperium propagavit quique caeli altitudines immensas peracutatus mundi spatia ampliora gentibus patefecit. Valeat.

*Datum Cantabrigiae  
a. d. viii Kal. Decembris  
A. S. MDCCCXCII.*

Mr. F. Darwin has been appointed Deputy Professor of Botany for the current academical year, Prof. Babington being unable to lecture on account of the state of his health.

NO. 1204, VOL. 47]

### SCIENTIFIC SERIALS.

*American Journal of Science*, November.—Unity of the glacial epoch, by G. Frederick Wright. An examination of the evidence in favour of two successive glacial epochs separated by an inter-glacial epoch, during which the glaciated area was as free from ice as it is at the present time. This evidence is shown to be inconclusive, at least as far as American observations go.—A photographic method of mapping the magnetic field, by Charles B. Thwing. Iron filings are strewn upon the film side of a dry plate laid horizontally in a magnetic field, and the plate is exposed to light from above. The filings are then brushed off, and the plate developed. From the negatives excellent lantern slides may be obtained.—Contributions to mineralogy, No. 54, by F. A. Genth, with crystallographic notes by S. L. Penfield. Description and analysis of agulante, metacinnabarite, dollingite, rutile, danalite, yttrium-calcium fluoride, cyrtolite, lepidolite, and fuchsine.—The effects of self-induction and distributed static capacity in a conductor, by Frederick Bedell, Ph.D., and Albert C. Crehore, Ph.D.—The quantitative determination of rubidium by the spectroscope, by F. A. Gooch and J. I. Phinney. The method is that of comparing photometrically the intensity of a certain line in the spectrum of the metal under investigation with the intensity of that given by a standard solution containing a known amount of the metal. A definite amount of the salt solution—usually the chloride—is taken up by a hollow coil of platinum wire, which may be made to take up constant quantities of liquid by taking care to plunge the coil while hot into the liquid, and removing it with its axis inclined obliquely to the surface. The coils were made of platinum wire 0.32 mm. in diameter, wound in about thirty turns to a spiral 1 cm. long by 2 mm. across, and twisted together at the ends to form a long handle. Each coil held 0.02 gr. of water. With such a coil, the blue rubidium lines were produced in a Muencke burner from 0.0002 mgr. of the chloride. Some test experiments showed that in the case of pure solutions of rubidium chloride the percentage could be found spectroscopically up to 1 part in 30,000 with an error as low as 1.25 per cent. In presence of potassium or sodium, however, the error may be as great as 20 per cent.—Notes on the meteorite of Farmington, Washington County, Kansas, by H. L. Preston.—A note on the cretaceous of North-western Montana, by H. Wood.—A deep artesian boring at Galveston, Texas, by R. T. Hill.—Notice of a new Oriskany fauna in Columbia County, New York, by C. L. Beecher, with an annotated list of fossils, by J. M. Clarke.—Description of the Mount Joy meteorite, by E. L. Howell.—Influence of the concentration of the ions on the intensity of colour of solutions of salts in water, by C. E. Linebarger.

### SOCIETIES AND ACADEMIES

#### LONDON

Royal Society, November 17.—"Stability and Instability of Viscous Liquids," by A. B. Basset, F.R.S. (Abstract).—The principal object of this paper is to endeavour to obtain a theoretical explanation of the instability of viscous liquids, which was experimentally studied by Professor Osborne Reynolds.

The experiment, which perhaps most strikingly illustrates this branch of hydrodynamics, consisted in causing water to flow from a cistern through a long circular tube, and by means of suitable appliances a fine stream of coloured liquid was made to flow down the centre of the tube along with the water. When the velocity was sufficiently small, the coloured stream showed no tendency to mix with the water, but when the velocity was increased, it was found that as soon as it had attained a certain critical value, the coloured stream broke off at a certain point of the tube and began to mix with the water, thus showing that the motion was unstable. It was also found that as the velocity was still further increased the point at which instability commenced gradually moved up the tube towards the end at which the water was flowing in.

Professor Reynolds concluded that the critical velocity  $W$  was determined by the equation

$$Wap/\mu < n,$$

where  $a$  is the radius of the tube,  $p$  the density, and  $\mu$  the viscosity of the liquid, and  $n$  a number; but the results of this

*Phil. Trans.* 1883, p. 615.

paper show that this formula is incomplete, inasmuch as it does not take any account of the friction of the liquid against the sides of the tube.

In the first place, if the surface friction is supposed to be zero, so that perfect slipping takes place, the motion is stable for all velocities. If  $\epsilon''$  be the time factor of a disturbance of wave-length  $\lambda$ , the value of  $k$  is

$$k = -\frac{2\pi W}{\lambda} - \frac{\mu}{\rho a} \left( \frac{4\pi^2 a^2}{\lambda^2} + n^2 \right) \quad (1),$$

where  $n$  is a root of the equation  $J_1(n) = 0$ .

Experiment shows that when the velocity is greater than about six inches per second, the frictional tangential stress of water in contact with a fixed or moving solid is approximately proportional to the square of the relative velocity. This introduces a constant  $\beta$ , which may be called the coefficient of sliding friction, whose dimensions are  $[ML^{-2}]$ , and are therefore the same as those of a density. This constant may have any positive real value,  $\beta = 0$  corresponding to perfect slipping or zero tangential stress, whilst  $\beta = \infty$  corresponds to no slipping, which requires that the velocity of the liquid should be the same as that of the surface with which it is in contact. Owing to the intractable nature of the general equations of motion of a viscous liquid, I have been unable to obtain a complete solution, except on the hypothesis that  $\beta$  is an exceedingly small quantity. This supposition, I fear, does not represent very accurately the actual state of fluids in contact with solid bodies, but at the same time the solution clearly shows that the instability observed by Prof. Reynolds does not depend upon viscosity alone, but is due to the action of the boundary upon a viscous liquid.

To a first approximation, the real part of  $k$  is proportional to

$$\frac{W\beta a}{\mu} - \frac{(n^2 + m^2 a^2)^2}{4n^2} \quad (2),$$

where  $2\pi/m$  is the wave-length of the disturbance, and  $n$  is a root of the equation  $J_1(n) = 0$ . Since the second term is a number, this shows that the motion will be stable, provided

$$W\beta a/\mu < \text{a number}$$

The experiments of Prof. Reynolds conclusively show that the critical velocity at which instability commences is proportional to  $\mu/a$ , and the fact that the theoretical condition of stability turns out to be that  $W\beta a/\mu$ , multiplied by a quantity of the same dimensions as a density, should be less than a certain number, appears to be in substantial agreement with his experimental results.

The results of the investigation may be summed up as follows—

(i) The tendency to instability increases as the velocity of the liquid, the radius of the tube, and the coefficient of sliding friction increase, but diminishes as the viscosity increases.

(ii) The tendency to instability increases as the wave-length ( $2\pi/m$ ) of the disturbance increases.

The remainder of the paper is occupied with the discussion of a variety of problems relating to jets and wave motion.

I find that when a cylindrical jet is moving through the atmosphere, the tendency of the viscosity of the jet is always in the direction of stability. The velocity of the jet does not affect the stability unless the influence of the surrounding air is taken into account, if, however, this is done, it will be found that it gives rise to a term proportional to the product of the density of the air and the square of the velocity of the jet, whose tendency is to render the motion unstable. The tendency of surface-tension (as has been previously shown by Lord Rayleigh) is in the direction of stability or instability according as the wave-length of the disturbance is less or greater than the circumference of the jet.

If in addition, the jet is supposed to be electrified, the condition of stability contains a term proportional to the square of the charge multiplied by a certain number,  $\kappa$ . When the ratio of the circumference of the jet to the wave length is less than 0.6,  $\kappa$  is positive, and the electrical term tends to produce stability; but when this ratio is greater than 0.6,  $\kappa$  is negative, and the electrical term tends to produce instability. It must, however, be recollected that when the above ratio is greater than unity, the tendency of surface tension is to produce stability,

but if the influencing body is capable of inducing a sufficiently large charge, the electrical term (when  $2\pi a > \lambda$ ) will neutralize the effect of surface tension and viscosity, and the motion will be unstable.

The well-known calming effect of "pouring oil on troubled waters" has passed into a proverb. The mathematical investigation of this phenomenon is as follows—The oil spreads over the water so as to form a very thin film, we may therefore suppose that the thickness  $l$  of the oil is so small compared with the wave-length that powers of  $l$  higher than the first may be neglected. Also, since the viscosity of olive oil in C.G.S. units is about  $1/325$ , whilst that of water is about 0.014, the former may be treated as a highly viscous liquid, and the latter as a frictionless one.

The result is as follows—

Let  $\rho_1, \rho$  be the densities of the water and oil,  $T_1$  the surface tension between oil and water,  $T$  the surface tension between oil and air,  $\mu$  the viscosity of the oil, and  $\epsilon''$  the time factor, then, to a first approximation,

$$k = -\frac{\{g(\rho_1 - \rho) + T_1 m^2\}(g\rho - T m^2)l}{4\mu\{g\rho_1 - (1 - J_1)m^2\}}$$

For olive oil,  $T_1 = 20.56$ ,  $T = 36.9$ , so that  $T > T_1$ , and I find that the motion will be stable unless the wave length of the disturbance lies between about 9/11 and 6/5 of a centimetre. This result satisfactorily explains the effect of oil in calming stormy water.

University Junior Scientific Club, October 26.—Mr E. I. Collis, in the absence of Mr Bourne, gave an exhibit of *Codium tomentosum*—Mr F. C. Britten gave an exhibit of the nest of a trapdoor spider—Mr Hill read an interesting paper on the determination of sex, which was followed by a long discussion—Mr Fisher exhibited some specimens of crystallized anhydrous oxalic acid, and described their methods of preparation.

#### CAMBRIDGE

Philosophical Society, October 31.—Prof G. H. Darwin, President, in the chair.—The following officers were elected for the ensuing session—President, Prof Hughes; Vice Presidents, Dr Cayley, Prof G. H. Darwin, Dr Hill; Treasurer, Mr R. T. Glazebrook; Secretaries, Dr Hobson, Mr J. Larmor, Mr Bateson; New Members of Council, Prof Thomson, Mr F. Darwin, Dr Shore, Mr Ruhemann.—The retiring President addressed the Society.—The following communications were made—Note on the determination of low temperatures by platinum-thermometers, by Mr E. H. Griffiths and Mr G. M. Clark. The authors, following up the suggestion of Profs Dewar and Fleming, that the resistance of certain pure metals vanishes at absolute zero, have assumed the possibility of extrapolating the platinum thermometer formulae, and have thus found the temperature at which  $R=0$ . From the previously-published constants of seven different thermometers—including Callendar's original wire—the mean value deduced by them is  $-273^\circ.86$ , which is in remarkable agreement with Joule and Thomson's thermodynamical value  $-273^\circ.7$ . They further suggest that the simple method of determining the resistance in ice and steam and assuming  $R=0$  when  $t = -273^\circ.7$  is sufficient to graduate a thermometer constructed of fairly pure wire, as they show that the errors so introduced will only amount to a fraction of a degree over the range  $-273^\circ.10$  to  $+150^\circ$ .—Carnot's principle applied to animal and vegetable life, by Mr J. Parker. The author discusses the question whether the conditions of the growth of plants are limited by the law of entropy. The assumption is made that Carnot's principle takes account only of the exchange of heat, and the temperature of the material system at which the exchange takes place, that the differential effect of solar radiation of different kinds consists in variation of the activity but not of the mechanical type of the growth. The increase of available energy due to the building up of inorganic materials into a plant can then only be explained, in conformity with the second law of thermodynamics, by the aid of differences of temperature during growth; the author gives calculations to prove that the difference between day and night is amply sufficient for this purpose.—Note on the geometrical interpretation of the quaternion analysis, by Mr J. Brill.

Tables are given of coefficients of expansion of carbon dioxide under pressures ranging from 50 to 1000 atm, and temperatures up to 258°, and for oxygen, hydrogen, nitrogen and air, under pressures up to 3000 atm. For CO<sub>2</sub> the coefficient has a maximum at a certain pressure for each range of temperature. This maximum corresponds to a higher pressure as the temperature rises. For the other gases the coefficient decreases regularly as the pressure increases. As regards temperature, the coefficient of expansion of CO<sub>2</sub> for each pressure reaches a maximum at a certain temperature and then decreases. This temperature is the higher, the greater the pressure. The more permanent gases behave as if they had already passed their maximum.—Study of the pathogenic power of fermented beet root pulp, by M Arloing.—Observations of the new comet Holmes (1892), made at the Paris Observatory (west equatorial), by M G Bigourdan (see Astronomical Column).—Transformation of the great telescope of the Paris Observatory for the study of radial velocities of the stars, by M H Deslandres (see Astronomical Column).—Summary of solar observations made at the Royal Observatory of the Roman College during the third quarter of 1892, by M P Tacchini.—On the inversion of Abelian integrals, by M E Gourat.—On the summation of a certain class of series, by M d'Ocagne.—On the equations of dynamics, by M R Liouville.—Experimental researches on the deformations of metallic bridges, by M Rabut.—Conditions of equilibrium and of formation of liquid microglobules, by M C Malévez. The following experimental results were arrived at. When a liquid spreads over the free surface of a denser liquid, microglobules are produced on inverting the position of the two liquids. If a liquid rests in drops on the surface of a denser liquid, then in the inverse position the denser will spread over the less dense liquid.—Demonstration of the existence of interference of electric waves in a closed circuit, by means of the telephone, by M R Colson. A Ruhmkorff coil was kept vibrating at 130 per second by a thermopile. To one of its terminals was attached a copper wire ending in a hook, to which a linen thread soaked in calcium chloride was attached by one end, the other hanging free. One of the terminals of a telephone was placed in contact with the thread, the other terminal being isolated. Under these conditions, the sound in the telephone was completely extinguished at a certain distance from the copper. When both the ends of the thread (which was 3 m long) were connected up by fine copper wires, two points of extinction were reached, one from each end. On shortening the thread these points approached each other and formed a zone of extinction between them. This zone of extinction spread over the entire copper wires as the thread was shortened to zero. The neutral zone is due to interference of two waves of the same period and of equal potential meeting in opposite directions.—On the co existence of dielectric power and electrolytic conductivity, by M E Cohn.—Observations on the preceding communication, by M. Bouty.—Magnetic properties of bodies at different temperatures, by M P Curie. These were measured by bringing samples of the bodies between the ends of two electromagnets inclined to one another, and measuring the forces experienced by means of a torsion balance. The bodies were heated in a porcelain crucible, the heat being supplied by platinum wires carrying a current, and measured by a Chatelier thermocouple.—On the propagation of vibrations through absorptive isotropic media, by M. ## CHEMICAL LECTURE EXPERIMENTS

*Chemical Lecture Experiments* By G S Newth (Longmans, 1892)

"ON revient toujours," &c and the very description of a good lecture experiment to one who had for thirty years always enjoyed performing an old one, and was overjoyed in bringing out a new one, is something akin to that of the old war-horse when he scents the battle from afar. And both Mr Newth's experiments and his descriptions are good, so I think that not only the novices of the profession but the old hands will read this book—the first with profit with a view to what they will do, and the second with pleasure in recollecting what they have done. I was dining some years ago with the great Dumas (I don't mean either of the novelists), and after dinner we sat together on the sofa smoking our cigars, when he said to me, "I have been in many positions—professor, minister of state, and investigator—and I have seen the world from many points of view. If I had to live my life again I would not leave my laboratory. The greatest pleasure in my life has been original work, the second greatest that of teaching a class who appreciated what I was telling them." We all know that Dumas was a master in the art of experimental teaching, and those who have practised this art, even at a great distance from the master, will agree with him that the pleasure of giving a well-illustrated experimental lecture on chemistry is not a small one, and even that a man may go on for thirty years and yet not be altogether tired of the job. The reason for this is not far to seek. Our science in its daily progress constantly opens up new paths which yield matter suitable for lecture experiment, and this gives a zest to the discourse unattainable by the teachers of most other subjects. Mr Newth has collected an ample store, and he has described them clearly. For the collection he has had favourable opportunity, to begin with he was a distinguished student at Owens, and there he may have picked up a few wrinkles, then he has for many years been Lecture Demonstrator to Frankland and Thorpe, and from them the wrinkles he has picked up have certainly been many. But although doubtless some are of his own finding out, I think it would have been well if he had added after the description of each experiment the name of the authority with whom it originated. Thus some have been described by the chemists I have named, others owe their existence to Hofmann, Bunsen, and others. These additions are not only due to the authors, but would add to the interest of the book. Mr Newth should see to this in the next edition. The old booksellers tell us that Faraday's "Manipulations" is a work which no lecturer should be without, and as everything which that prince of experimenters wrote or did is worthy of attention, they speak truly, and yet no modern chemists can be bound by Faraday's experience of sixty years ago. Things are not as they were; and the methods of work and the illustrations of chemical phenomena which he details belong to a bygone age. And so Mr. Newth

comes forward to give the lecturer of to-day a helping hand. The first thing that strikes one on looking through his pages, is how simple are the experiments—so far as illustrating the chemistry of the non-metals goes, and he goes no further—needed to illustrate a course of lectures. We do not require the expensive and delicate instruments of the physicist. With glass and india-rubber, as Liebig said, we chemists perform all our mysteries. Only in a few cases, as, for instance, when we want to hand round wine-glasses filled with liquefied oxygen or air, or when we desire to show our students free fluorine and such like things, does the apparatus become expensive or the experiments troublesome. All the ordinary and many of the extraordinary experiments detailed in the book may be carried out with little cost and without great trouble, indeed most of them may be made by the veriest tyro provided he stuck to the letter of the description and does not attempt to vary the proceedings, as one I knew did, who thought that as sulphuric acid is a more powerful desiccating agent than lime, he would dry his ammonia by the former substance instead of by the latter material. No account of any experiment, the author tells us, has been introduced upon the authority solely of any verbal or printed description, but every experiment has been the subject of his personal investigation and the illustrations are taken from his original drawings, so that we may be sure that every experiment will "go" if properly managed and fairly dealt with. Many of the experiments are, of course, old staggers, but none the less useful, whilst others are new to me and probably to most people. To mention many either old or new this is not the place, but one of them, which has struck me as interesting is an easy method of showing the freezing of water by its own evaporation first with a common air-pump, and second with no air-pump at all. I always used a Carre's machine, by which a quart of water could be frozen, but Mr Newth gives an excellent description of how a beautiful icicle twenty to thirty centimetres long can be obtained both with and without an air-pump. The secret of how to do this can best be learnt by reading pages 57 to 59 of the book. "How to float soap bubbles upon carbon dioxide" has often proved a difficult question to answer experimentally, because if you managed, after a score of trials, to free your bubble from the pipe on which you blew it, the bubble usually bursts the moment it touches your heavy gas. Mr Newth lets us into the secret. You must remove every trace of hydrochloric acid, which is carried over with the gas, by washing, the presence of this acid being fatal to the life of a soap bubble. Under chlorine (p 88) a description is given of the mode of sealing up bulbs filled with chlorine and hydrogen. This was first done in the early sixties by my old helper and friend Mr. Joseph Heywood, of Owens, to whom both students and lecturers owe many an ingenious and striking experimental illustration. As Mr Newth remarks, there are many obvious reasons why the old plan of filling a soda-water bottle with a mixture of equal volumes of the gases and then throwing it out of the lecture-room window into the street, if the sun happened to shine, is "unsuitable for a lecture experiment," and Heywood's bulbs answer the purpose better in all respects. The author does not tell us—as he ought to have done—

that Victor Meyer now seals up bulbs of oxygen and hydrogen (electrolytic gas) in a similar way, and that these, like their confrères of Cl and H, can be kept not only in the dark for any time, but, unlike these, also in the light without undergoing any change. "The fact that many gases when perfectly dry do not combine is illustrated by the case of chlorine and metals—brass and sodium, pp 84 and 85—as well as of carbon monoxide and oxygen, for these gases will not explode if dry, p 189. A more striking way of illustrating this latter case than that with the eudiometer is not mentioned. I will add it. Dry a current of carbonic oxide over glass balls moistened with strong sulphuric acid, light the stream of gas issuing from a horizontal tube, then plunge over the blue flame a cylinder full of air which has been previously dried by shaking it up with a little strong sulphuric acid. The flame instantly goes out. Another case of the kind observed by Arnold lends itself to a lecture experiment. He found that powdered iron will not burn in pure dry oxygen, and in order to be able to estimate hydrogen in iron it was found necessary to insert a small tube containing a drop of water, through which the oxygen passed before coming into contact with the iron, this tube being of course weighed both before and after the experiment. This may well be included in the next edition, which I hope will soon be called for. Another capital experiment to show that iron can be carbonized by contact with a diamond was recently described to me by Mr Gilbert Fowler, of Owens. A loop of pure thin iron wire is placed in a vertical glass tube surrounded by an atmosphere of hydrogen. Below the loop is a splinter diamond (or some diamond dust) placed on the top of a glass rod working through the lower end of the tube. After heating the wire by a current to the highest possible temperature without fusion, bring the diamond carefully into contact with the heated iron. The metal at once fuses. But of good experiments "there is no end" (Mr Newth describes 620 for the non-metals alone) whilst of a review of a book in NATURE there must be a speedy end, and I will end by advising all those who like to see and to show good experiments to get Mr Newth's book.

H E ROSCOPÉ

#### A MANUAL OF PHOTOGRAPHY

*A Manual of Photography.* By A. Brothers, F R A S  
(London: Charles Griffin and Co, 1892)

MR BROTHERS has in this well-illustrated book brought together a great amount of information relative to the history, processes, apparatus, materials, &c, which will be welcomed by all who are interested, even if only in a general way, in the fascinating art of photography. The work covers about 360 pages, is divided into five parts and is accompanied by a full index.

In the short historical sketch which is introduced as the opening chapter, the author by means of quotations and otherwise gain much information which is not readily accessible, and many facts that are not inserted in our treatises, and which consequently are not generally known. At the present day, when so many possess a

camera of some sort or other, it is very curious to carry ourselves back to the time of Daguerre and to picture to ourselves the idea which he put forward when he wrote in his pamphlet, "Those persons are deceived who suppose that during a journey they may avail themselves of brief intervals while the carriage slowly mounts a hill to take views of a country." Whether this is or is not the case now we will not stop to discuss, but we may mention that many other very interesting extracts are made from the same source.

The next three chapters deal with the chemistry, optics, and light as applied to photography. In these there seems to be nothing that calls for special attention, unless it be to state that the author has written them in a charming manner, as for instance the short summary under the heading "Magnesium Light," which one reads with quite renewed interest.

Coming now to Part II, Processes, we find the most important section of the whole book. As Mr Brothers rightly observes, the old processes previous to the introduction of the gelatine bromide methods have been put completely in the shade, not because they have been surpassed by better and more trustworthy ones, but simply because they require a little more care in manipulation and consequently the consumption of more time. In order to remedy this to some extent he has given great prominence to them, devoting nearly 140 pages to them, including working details of the more important later processes. For the sake of facility of reference they are arranged in alphabetical order, and in many cases they are accompanied by illustrations which show the actual results that can be obtained by the uses of the methods under consideration. To cite them in anything like detail would carry us too far away, but we may mention one or two briefly. The (wet) collodion process is of course here fully described; the author lays special stress on the advantage of this process, for there is no doubt that where dry plates are now used far better results could be obtained by employing this old wet process. The photo-mechanical process, collotype, receives also a rather lengthy description, but its utility and the excellence of the results obtained necessarily give it some prominence. A specimen illustration of the last mentioned is inserted, as well as one of a recent application of this method for printing in colour. Printing on wood, photo-lithography, *platinotype*, &c, together with photogravure, Woodbury type and a host of others, are all described, some briefly, others of greater importance somewhat more in full.

Parts III and IV deal with the apparatus and materials used in the production of a finished picture. In the former the author describes the particular characteristics of many of the various kinds of cameras and accessories, while in the latter are explained the chief uses and actions of the chemicals employed.

Part V, the last, contains short notices of the applications to which photography has given rise. Astronomical Photography is referred to at some length, and we may mention that we have an excellent reproduction of one of Mr Rutherford's beautiful lunar photographs taken at first quarter. The practical

hints in the concluding chapter should be found very serviceable

Mr Brothers has produced a very serviceable and useful addition to our photographic literature; as a handbook for students it perhaps is somewhat too bulky, but nevertheless it will be very much used by them. Every photographer who wishes to know something about the art with which he is working, and who does not wish to limit himself to the mere cut-and-dried manipulations, should at any rate make himself acquainted with the volume.

W J L

### MATRICULATION CHEMISTRY

*Matriculation Chemistry* By Temple Orme (London Lawrence and Bullen, 1892)

THIS is still another elementary manual dealing with the non-metals and their compounds. According to the author it can be studied most advantageously if the rudiments of chemistry have first been acquired. The book is built on pretty much the same plan as many already in existence, here and there, however, the reading is enlivened by ideas which, if not altogether commendable, have some pretensions to novelty.

The author is evidently of opinion that much of the ordinary chemical knowledge can be presented in other ways. Mass and weight first receive attention. In this book there are no atomic weights, atomic masses reign supreme. In using a balance we are told that we do not find weights, but "only masses." Indeed to bring this idea home the following curious question is set—"When you 'weigh' a thing in an ordinary balance, do you find its weight?"

After a passing allusion to constitutional formulæ, in which they are likened to pyrotechnic frames, the next important alteration with which the author concerns himself refers to the nomenclature of oxides. Such a name as sulphur dioxide or carbon dioxide is discarded, for it is "founded upon a formula which is liable at any time to be altered so as to suit our knowledge of atoms and molecules." Anhydride is described as, "etymologically at least, a still more atrocious term", hence we find that throughout the book  $\text{SO}_2$ ,  $\text{CO}_2$ , &c, are spoken of as acids.  $\text{P}_2\text{O}_5$  is said to be a tribasic acid,  $\text{N}_2\text{O}$  a monobasic acid.  $\text{CS}_2$  is called sulphocarbonic acid,  $\text{P}_2\text{S}_5$  thiophosphoric acid,  $\text{N}_2\text{O}$  hyponitrous acid, and so forth, in spite of the fact that such compounds as that formed from "hydric oxide and phosphoric acid (*sic*) are often called acids by modern chemists."

The definition of a salt is thus summarily disposed of—"You are often asked what a salt is, the only possible answer is that it is a compound."

Such methods of tampering with terms which have a generally-accepted meaning should, it seems to us, meet with no encouragement. They can only end in muddling the reader who wishes to pursue his subject by the aid of any of our standard works. But matter which is liable to do more immediate harm is frequently to be noted. For instance, it is stated that there is no such thing as the Law of Multiple proportions—it is only a corollary of

the atomic theory. If, according to its usual interpretation, a law is a generalized statement of fact, it is rather hard to see how its existence is affected by its relations to any theory.

To most chemists the brilliant work of Moissan has sufficed to settle the question of the isolation of fluorine, the author is, however, still sceptical on this point.  $\text{P}_2\text{O}_3$  is given as the formula of phosphorous acid (*sic*), recent research has shown  $\text{P}_4\text{O}_6$  to be correct. The valency of potassium is said to have been fixed by a "minute study of its gaseous compounds," water is stated to be elastic with regard to shape, and from Avogadro's hypothesis molecules of different gases are stated to be equal in size.

Even when the author is apparently trying to be precise he is apt to mislead. The following definition is an example—"A chloride means a compound of chlorine with some other substance which, though it is not itself metallic in its general characteristics, possesses that important property of a metal, the capability of uniting energetically with chlorine." Is it to be understood from all this that a chlorine compound which is not produced by energetic union—say an endothermic compound like  $\text{C}_2\text{Cl}_4$ —is not a chloride?

These extracts may serve to show that the book requires to be carefully overhauled before it can be placed with confidence in the hands of a beginner.

### OUR BOOK SHELF

*Vegetable Wasps and Plant Worms, a Popular History of Entomogenous Fungi, or Fungi parasitic upon Insects* By M C Cooke, M A, LL D, A L S [364 pp + 4 pl and figs in text] (London S P C K, 1892)

It is somewhat surprising that a book on a subject of such importance alike to the entomologist and fungologist has not been forthcoming long ago. It is true that a Memoir on the subject was undertaken thirty-five years ago by Mr G R Gray, but, being privately printed, was limited in circulation. To this work Dr Cooke admits his indebtedness for a large amount of information bearing on the entomological aspect of the subject, and it is to be regretted that he was not aware of the existence of a much extended manuscript revision of the same work, at present in the Botanical Department, Natural History Museum.

Dr Cooke's book is professedly a popular work on the subject, and consequently does not deal with the economic side, relating to such matters as the "muscardine" or silkworm disease, further than to indicate the nature and affinities of the fungus causing the disease.

The fungi parasitic upon insects are arranged under four primary groups, the *Cordyceps* group, the *Laboulbeniaceæ*, the *Entomophthoræ*, and lastly a heterogeneous collection of moulds, which, with few exceptions, are not truly parasitic and destructive. The structure and general characteristics of these groups, with glimpses of their life-history, are dealt with in an introductory chapter. Entomologists, whose main interest will be to ascertain the name of any fungus parasitic on an insect, will find this a comparatively easy matter, as the general arrangement is an entomological one, commencing with the Hymenoptera, and under each is given an account of all the fungi that are known to be parasitic upon species included in the order. Numerous woodcuts in the text and four plates assist very materially in the determination of species. From the mycological standpoint the arrangement indicated above is purely artificial, and introduced

for a purpose, while for the benefit of those who desire to know more of the inter-relationship of the fungi enumerated, a classified list is given of all the species, arranged under their respective families, including the distribution and name of the host.

For the general reader, who is not specially interested in either insects or fungi, there is a considerable amount of interesting information bearing on such subjects as vegetable caterpillars, vegetable wasps, foul-brood of bees, &c, and the interest is not lessened by following the transition from the romantic and highly imaginative accounts given by early travellers of these productions, to the statements in accordance with modern knowledge. There is a slip on p. 35, *Cordyceps Sheeringii* should be *C. Sherringtonii*. The indices are very complete and the figures, excepting one on p. 10, good.

*Notes on Qualitative Chemical Analysis* By P. Lakshmi Narasu Nayudu, B.A. (Madras K. Murugesu Chetty, 1892.)

IT is interesting to meet with books such as this, which serve to indicate how the study of chemistry is progressing in the colonies and dependencies of the empire.

The author sets out with the endeavour to keep the rationale of the various processes of qualitative analysis well to the front, as in this way he considers the value of the study as a means of scientific training can alone be brought out. Group-reagents and the reasons for their use are first discussed as a preliminary to a somewhat exhaustive study of the reactions of the different basic and acid radicles. At the end of each group tables are given showing at a glance the behaviour of the radicles towards the various reagents.

It is somewhat astonishing that after such a minute study of the reactions of all the more common radicles, the author should give no schemes for the separation of the constituents of the different group-precipitates. In spite of the fact that under each radicle he gives as many, if not more, reactions than are given in the larger works on qualitative analysis, he contents himself with merely going through the examination of a simple salt. The expenditure of but little space would remedy this omission, which limits the sphere of usefulness of the book. It is to be noted also that film-tests find no place in the system adopted.

It may be said that the author adheres well to his purpose of showing why any particular operation is performed. The book contains a large amount of useful information. Occasionally, however, the mode in which it is stated is peculiar. "In the cold" is an expression commonly used in speaking of a reaction. The use of "in the heat," a term often employed by the author, is, on the other hand, uncommon. To speak, too, of "neutral solutions of zinc salts containing strong acids" is confusing. In some cases, as when using bodies like potassium metantimoniate or sodium hydrogen tartrate, it would be advisable to give the name as well as the formula; it isn't every student who is acquainted with such substances. It is erroneous to say that fluorine does not combine with carbon even at a high temperature. According to Moissan, all the allotropes of carbon, except the diamond, unite with fluorine, indeed some of the forms are, in the cold, spontaneously inflammable in the gas.

The following typographical errors are omitted in the list of errata. On p. 47 "materially" should be "materially," " $\text{gSO}_4$ " &c should be " $\text{MgSO}_4$ " &c on p. 58, and " $\text{Ba}_2\text{P}_2\text{O}_7$ " is given for " $\text{Ba}_2\text{P}_2\text{O}_7$ " on p. 69.

*Science Instruments.* Catalogue of Scientific Apparatus and Reagents manufactured and sold by Brady and Martin. (Newcastle-on-Tyne, 1892.)

AT the present time, when almost all branches of experimental science are growing so rapidly, and new and improved pieces of apparatus are continually coming

into existence, it is satisfactory to find that instrument makers are trying to keep pace with the times, and to afford purchasers the means of ascertaining with the minimum trouble what apparatus can be obtained to serve a particular end. This catalogue is an instance that such is the case. It is a well-bound book, profusely and clearly illustrated. The different kinds of apparatus, useful both for teaching and for technical purposes, are well classified. To prevent mistakes in ordering, each piece of apparatus is separately numbered, and where a new form is figured, a few lines are added explanatory of the principle involved.

The instruments quoted belong to various branches of experimental science—chemistry, bacteriology, physics, mechanics, and meteorology. A selection of instruments made by the Cambridge company, and miscellaneous apparatus, diagrams, chemical reagents, &c, are also included.

The sections on bacteriology and gas analysis are especially full, and indicate the interest at present taken in these departments.

A table of contents and an index are supplied. On p. 145 "Irish" is misprinted for "Iris", and what is termed an "optical bank," on p. 164, is usually called an "optical bench."

## LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

### Universities and Research.

AT the discussion in Edinburgh on the proposed National Laboratory, Lord Kelvin and Sir Geo. Stokes took marked exception to my contention that the primary business of Universities was research, contending that it was teaching. In a sense their contention is true, but not in contradistinction to my contention. The distinction would hardly be worth fighting over were it not that they took up the further ground that only those researches should be engaged in in Universities which were likely to interest the students. Of course the leaders of science can if they choose sell the great birthright of Universities for a mess of pottage, but I hope they will not be permitted to do so without protest. What view the democracy take of Universities is of the very last importance with our democratic institutions, and I trust all those who have the welfare of the nation at heart will protest against the Universities being turned into coach houses. In this connection it is most important to bear in mind the distinction between the functions of Universities and those of schools and colleges. The function of these latter is primarily to teach those who resort to them. The function of the University is primarily to teach mankind. In former days, when the means for distributing information were very imperfect, students used to flock from all sides to learn directly from a great mind. Nowadays the great mind distributes his teaching broadcast. In old days the only way to learn what was being done to advance knowledge was to go to the place where knowledge was being advanced. Nowadays we read the Transactions of our learned societies at home. But at all times the greatest men have always held that their primary duty was the discovery of new knowledge, the creation of new ideas for all mankind, and not the instruction of the few who found it convenient to reside in their immediate neighbourhood. Not that I desire to minimize the immense importance of personal influence, it is overwhelming; but it is a question quite beside the one at issue, which is whether the advance of knowledge by research and the teaching of the whole nation by the discoveries made is not rather the primary object of Universities than the instruction of the few students who gather in their halls; that is the real question at issue between Lord Kelvin, Sir Geo. Stokes, and myself. Are the Universities to devote the energies of the most advanced intellects of the age to the instruction of the whole nation, or to the instruction of the few

whose parents can afford them an, in some places fancy, education that can in the nature of things be only attainable by the rich?

In view of the discussion upon the proposed Teaching University for London it is to be hoped that these things will not be overlooked amid the local questions and rival institutions. It is to be hoped on the one hand that those who will have the privilege of learning in the greatest city in the world will not be deprived of the personal influence of its greatest men by relegating these to some haven of laboratories where no bracing breath of students shall interfere with the inmates. On the other hand it is to be hoped that London will so far honour itself as not to be content until it sees its University a centre of thought and investigation from which shall radiate new ideas and discoveries to enlighten and benefit the whole nation. Before I close there is a matter of great importance to which I fear sufficient importance is not attached by those who are directing this matter and that is the great objections there are to mixing up Universities and Colleges with examining boards. We here in Trinity College, Dublin, suffer very much from the fact that a considerable number [of our students never reside here, but only come over for periodical examinations. We only suffer in one way, while if London adopted this abominable arrangement it would suffer in two ways. We suffer because our degree is much less valued than it would be if all our students were compelled to reside. All our students have not that education got by friction with their fellows and by contact with trained intellects which no examination can test, and which is such a valuable training, and in consequence our degrees are the less valuable. London would suffer in this way, and it is a very serious way too. In addition to this London would suffer from the inordinate importance that would be attached to extern examiners if the University examined London and extern students. So far we have escaped this danger, but it is inevitable in London because the extern element there would be large, influential and organized, while with us it is of little strength. The result would be to perpetuate and intensify that horrible teaching for examinations which is so necessary an evil in the case of the majority of students, but from which the leaders of thought should be exempt. It matters not that the syllabus nor even that the very questions are approved by the professor, if the examination is conducted to any serious extent by an independent mind. The student will seek a coach, who will probably teach him very well indeed, but whose whole view of learning will be of the passing-examination type, and who will infect his pupil with this miserable disease. Gradually the professor himself will be involved in the vortex, and the whole University will gradually look upon the passing of examinations as the end of life for students, and this is the acme of coaching and the bathos of education.

Trinity College, Dublin, November 25

### The Stars and the Nile

AFTER reading Mr J Norman Lockyer's papers on the connection of the orientation of Egyptian temples with the heliacal rising of certain stars, I was interested to find that a custom still exists in the neighbourhood of the Second Cataract having a strong resemblance to the old Egyptian custom.

The Nuba people of this part foretell the first rise of the Nile by the heliacal rising of the Pleiades, or as they call it, "Turaya." For Sirius they have no special name, calling it merely "the driver" or "follower" of the three stars (Orion).

It must be remembered that the first sign of the rise at Wady Halfa occurs at the beginning of June, reaching Assouan about a week later, but for some days the increase is very slow, and scarcely perceptible except in the readings of the Nile gauges.

These Nuba people still preserve in their language many ancient Egyptian words, and possibly we may have here a trace of the old custom, the Pleiades being taken instead of Sirius on account of the earlier date of the rise in the district of the Second Cataract than in Egypt itself.

### A Palæozoic Ice-Age

THE account by Dr Wallace in NATURE (p 55) of glacial deposits recently discovered in Australia is a most important and welcome addition to our knowledge. But to us the surprising circumstance is that Dr. Wallace appears quite unaware of the fact that this is only an addition to a great series of discoveries, by no means confined to Australia, affording evidence of a Palæozoic ice age. That the deposits near Sandhurst are Palæozoic may, in the absence of any indication to the contrary, be assumed, since they are clearly similar in position and character to the well-known boulder beds of Bacchus Marsh, and these have been correlated with the strata containing ice borne fragments, amongst the marine beds west of Sydney and also at Wollongong to the southward, and in Queensland to the northward. All these beds have been shown to be upper carboniferous. A good account of the facts known up to 1886 may be found in Mr R D Oldham's paper on the Indian and Australian coal-bearing beds (Rec Geo Surv Ind xiv p 39).

It is scarcely necessary to refer to the fact that extensive Palæozoic glacial deposits, of the same age as those of Australia, have been found in several parts of India, some as far within the tropic as lat 18° N., others in the Salt Range of the Punjab, that the famous Dwyka conglomerates of South Africa are similar and in all probability contemporaneous, and that boulder beds of very possibly the same geological date have been observed in Brazil. We should not have mentioned these but for the fact that the idea of a Palæozoic ice age is apparently novel to Dr Wallace. We do not think, however, that the reason why so well-informed a naturalist is unacquainted with geological data long known to many is any mystery. It has become an accepted article of faith amongst most European geologists (there are, of course, exceptions) that no ice age occurred before the last glacial epoch, just as it is part of the geological creed that the carboniferous flora was of world-wide extension, and as it has become the prevailing belief that the deep oceans have been the same since the consolidation of the earth's crust. Now the discoverers of glacial evidence in the carboniferous beds of India and Australia also assert that the carboniferous flora of those countries differed *in toto* from that of Europe and resembled the jurassic flora of European regions, and some of them add that the great southern flora of South Africa, India, and Australia must have inhabited a vast continent, part of the area of which is now beneath the depths of the Indian Ocean. Partly from Indian and Australian geologists being regarded as heretics geologically, partly from other causes, the evidence of ice action in India and Australia has been generally ignored. No better proof could be afforded of the fact that European geologists in general have omitted to notice the series of discoveries in the southern hemisphere and in India than the publication of Dr Wallace's paper.

The glacial evidence as it now stands is extremely interesting and perhaps transcends in importance that of the Pleistocene glacial epoch. For as the effects of the carboniferous ice-age were felt within the present tropics, either the earth's axis of rotation must have shifted considerably, or else the refrigeration of the surface must have been due to a cause distinct from that supplied by the late Mr Croll's theory, even when supplemented by Sir R Ball's amendment.

Our own interest in the whole subject is chiefly due to the circumstance that we happened in 1856 to be the first who met with the ancient boulder-bed in India, and suggested that it might be explained by the action of ice. The discoveries in Australia and South Africa were of course quite independent of those in India, but were, we believe, slightly later in date.

W T BLANFORD

HENRY F BLANFORD

### Geology of Scotland.

MAY I supplement Prof. Green's history of geological mapping in Scotland (NATURE, vol xlvii, p. 49) by pointing out that Mr Cruchley published, on March 23, 1840, "A Geological Map of Scotland by Dr MacCulloch, F.R.S., &c, published by order of the Lords of the Treasury by S. Arrowsmith, Hydrographer to the King." This fine map is on the scale of four miles to an inch. From the omission of "the late" before MacCulloch's name, it seems possible that the plates were in course of engraving before his death in 1835.

GRENVILLE A J. COLE

Royal College of Science for Ireland, Dublin

## British Earthworms

I ENTIRELY concur with Dr. Hurst's view that the supposed new species, described by the Rev Hilderic Friend as *L. rubescens* is in reality Savigny's *L. festinus*. I may add a further reason for discarding the term *L. terrestris*, Lin., and substituting *L. herculeus*, Sav., for our common large worm. Savigny himself used "Ention terrestris" to indicate a worm differing considerably from *L. terrestris*, Lin., in the position and extent of the clitellum, moreover it belongs to the genus *Allolobophora* and not to *Lumbricus* at all.

With regard to the second "new" species, *A. cambrica*, recently described by Mr. Friend, I believe that it is merely a variety of *A. chlorotica*, Sav.

According to the description it appears to differ from the latter species in three points—(1) colour, (2) extent of clitellum, (3) number of spermathecae.

(1) Now, amongst my collection of British worms I find one, of which a water colour sketch taken from the living specimen closely resembles Mr. Friend's description of the colour of *A. cambrica*. My notes as to size, habits, &c., agree with his description. I have carefully re-examined my specimen, and find that it agrees perfectly with *A. chlorotica*, or, in other words, I find that *A. chlorotica* may vary—as Hoffmeister knew that it did vary—so much as to resemble *A. mucosa*, and I may suggest that it is a mimetic resemblance.

(2) Further, with regard to the clitellum of *A. chlorotica*, in the table given by the Rev Hilderic Friend, it is stated to cover somites 29-36. As a matter of fact the next somite, 37, is nearly always included. This brings *A. cambrica*, Friend, into harmony with *A. chlorotica*, Sav.

(3) Thus the only differential character left is the number of spermathecae, and I cannot agree to the validity of a new species on this single character, several specimens should be examined to settle the point, as variation in this feature is known to occur.

I take a certain amount of credit to myself for the useful faunistic studies on the earthworms of Great Britain, now being pursued by the Rev Hilderic Friend, for, if I mistake not, I put him in the way of recognizing their specific characters, when, some years ago, I named for him, with remarks thereon, sundry consignments of some scores of worms which he sent to me for that purpose. WM. BLACKLAND BENHAM

The Dept. of Comparative Anatomy, Oxford,  
November 21

## Egyptian Figs

THE accompanying sketch represents an instrument used in Egypt for removing the "eye" or top of the sycomore fig. It is a piece of hoop iron, blunt on one edge and tolerably sharp on the other, and fixed into the end of a stick. The fruit of *Ficus sycomorus*, or "Egyptian fig," seems to be invariably infested with the insect *Sycophaga crassipis*, Westw., which I am informed by Rev T. F. Marshall, who has kindly given me the name, is the same insect supposed to effect capricification in Malta, judging from specimens which I sent him. This fig never produces ripe seed in Egypt, though it has been introduced from the earliest times. Not only are the ancient coffins made of the wood, but it was adopted as the sacred "Tree of Life"

It probably came from Yemen, where Dr. Schweinfurth saw many seedling trees growing spontaneously. The tree bears three crops per annum, in May, June, and August—September. Boys cut off the top of the figs of the first two crops only. Dr. E. Sickenberger, one of the professors in the School of Medicine, Cairo, informs me that the figs have no pleasant flavour until the operation has been performed—"They then become very sweet, but remain smaller than when not cut open. The object is to let the insects escape. Those that are left become watery and tasteless, and are full of mummies or sycophaga." In his first description Dr. Sickenberger described the instrument as "a kind of thimble made of iron plate

ending in a spatula like a finger-nail. It is fixed on the thumb of the right hand. The operation is only made on fruits which shall be picked up the following day. The day after the operation the fig is quite ripe. The male flowers in those figs are all aborted, and the females have never perfect seeds. The figs of the third generation are larger, of an agreeable taste, and sweet-centred, but they are not operated upon, only because in August and September, though the trees are much fuller of fruit than in May and June, the people have so much to do at that time. They are seldom sold, and only eaten by the owners of the trees, or else they are abandoned to the field mice, birds, and dogs, which latter are very fond of them. These *nilg* fruits are full of sycophaga."

It will be seen that the instrument he has sent me is of a different shape to the one he describes, and the chief interest lies in the fact that Pliny also describes the process as closely corresponding with this modern method. He even uses a similar term "nail" (*δρυχας*) *πείπειν οὐ δύναται ἂν μὴ δεικνυσθῇ ἀλλ' ἔχοντες δρυχας σιδηροῦς δεικνύουσιν* & δ' ἂν δεικνυσθῇ, *τετράταια πέπειται* (*Nat. Hist.* xiii. 14). Further, the Prophet Amos describes himself as *bōlās signum*, and the authors of the LXX, writing in Alexandria, appear to have understood the expression and translated these words by *κνίζων σινδύμματα*. This is the same verb as that which Pliny uses, so that it would seem to be pretty certain that Amos performed identically the same operation on the figs as is still done in Egypt at this day. It will be noticed that the idea was to ripen the figs. It does not really do this, because there are no seeds, but it does make the fig sweeter. It also liberates the insects, and without doing this the figs would be uneatable. Jerome is the only author, as far as I know, who alludes to "grubs" being inside the fig.

GEORGE HENSLAW

## Iridescent Colours

THE article "Iridescent Colours" on p. 92 puts me in mind of a notice which I published thirty years ago, while I lived in the United States. It was entitled "Harmonies of Form and Colour" (*Stettiner Entom. Zeitung*, 1862, pp. 412-414), and a portion of it refers to the subject of the above-mentioned article in NATURE, and may be of interest to its readers—

"A fundamental observation, which proves the influence of the intensity of light upon colour, may be made on some insects of metallic coloration, inhabiting a large area from north to south. About six years ago, while in Southern Russia, I took a walk during sunset, and was struck by the brilliancy of some metallic red *Chrysomela*, abundant in that locality. I found that it was the common *C. fastuosa*, which I did not recognize at once, because in the environs of St. Petersburg, where I lived at that time, it occurs in its metallic-green variety, with an iridescent blue stripe on each of the elytra. Still farther north it assumes a more violet metallic colour. The same is the case with *Chrysomela cerealis* and *C. graminis*. The first of these species is represented in St. Petersburg in the blue variety (*C. ornata*, Ahrens), while the typical variety, occurring farther south, has purplish-red metallic stripes. It is evident therefore that the metallic colouring of these wide-spread species is gradually intensified from north to south, in the order of the colours of the spectrum. We may imagine the area which these beetles occupy, like an immense rainbow, reflected from their backs, violet in the north, red in the south; the violet perhaps connected in some way with the magnetic phenomena prevailing in the polar regions. The longicorn beetle (*Callidium violaceum*) undergoes the same variation: violet in the north, blue in central Europe." C. R. OSTEN SACKEN

Heidelberg, Germany, November 27

## The Afterglow

THERE has been for three weeks past a very remarkable renewal of the afterglow. There is a quite deep secondary red glow after the stars are fully out. I should say that no such afterglow has been seen since 1886, or three years after the Krakatō eruption. There is also a great extension of the white hazy atmospheric corona around the sun, very marked also around the moon. I am unable, however, to make out any of the pink colour on the outer edge of the haze, which was so char-

acteristic of "Bishop's Ring," and distinguishable at Honolulu for two years. Apparently there has recently been a great reinforcement added to the material in the upper atmosphere, which produces the afterglows.

In this owing to the August eruption in Alaska, which is said to have distributed ashes at a distance of 250 miles?

Prof C J Lyons, in charge of tidal observations in Honolulu, reports the period of highest mean tide to have extended itself this year into November, or fourteen months later than the last similar period. The mean sea level is now over ten inches higher than it was last April. It is also somewhat higher than has been shown by any previous tide registers in Honolulu. Mr Lyons regards this as of special importance, taken in connection with the oscillation of the earth's axis, now established by the combined observations at Berlin and Honolulu.

Honolulu, November 8

SERENO E. BISHOP

### OSMOTIC PRESSURE

OF the various properties which have found a common explanation in the new theory of solutions, there are none perhaps to which more interest attaches than to osmotic pressure, and although, on account of the experimental difficulties, the observations as yet accumulated on this subject are but scanty, they have so largely contributed to the novel ideas involved in the new theory, that they merit special attention.

Since accounts of osmotic pressure are finding their way into few English text books, it may be worth while glancing at the main features which have led up to the present state of the question.

It has long been known that if an aqueous solution—say, of sugar—be separated from pure water by a piece of animal membrane, that movements of the water and of the sugar take place through the membrane. If the solution be contained in an open vessel, the base of which is composed of membrane, on partially immersing the vessel in water it is easy to see that more water enters the vessel than solution leaves it. The level of liquid within rises above that without the vessel, different pressures being thus set up on opposite sides of the membrane.

To this process wherein currents pass through a membranous septum, the terms "osmosis," "osmose," and "diomose" have been applied. The last of these is perhaps to be preferred, as it serves to indicate that two currents are involved in the phenomena. Investigations carried out as indicated above were concerned with the measurement of what was termed the "endosmotic equivalent." That is the ratio of the amount of water passing *into* the solution to the amount of dissolved substance passing in the opposite direction. Consistent measurements of this quantity could not be obtained, however, for it was found that the nature of the membrane exercised a marked influence upon its magnitude. The kind of membrane employed, or, with the same membrane, its thickness or freshness, or even the direction in which water passed through it, was of importance. Thus in illustration of the last point, water passes more readily outwards through eel's-skin, more readily inwards through frog's-skin.

To obtain quantitative relations in this field it thus became essential to eliminate the influence of the membrane, and more recently this end seems to have been attained by the use of membranes artificially prepared.

These artificial membranes differ from those of animal origin in the remarkable particular that although they allow water to pass through, they present a barrier to the passage of certain dissolved substances. On this account they have been termed semi-permeable membranes, and by their use measurements of osmotic pressure have been made possible.

To carry out such measurements the first point to be solved was to obtain a membrane of sufficient strength.

The substance which has been found to be most satisfactory as a membrane-former is copper ferrocyanide. When aqueous solutions of potassium ferrocyanide and copper sulphate are carefully brought into contact a pellicle of copper ferrocyanide is formed where the two solutions meet. In this condition the pellicle is much too fragile to sustain even slight differences of pressure, but by the following simple device, employed first of all by W. Pfeffer, satisfactory results have been obtained.

If a cell similar to the ordinary porous pot of a voltaic battery be lowered into a solution of copper sulphate while at the same time a solution of potassium ferrocyanide be poured into its interior, the two solutions meet somewhere within the walls of the cell and deposit a film of copper ferrocyanide. Little diaphragms of membrane are thus produced stretching across the pores of the cell-wall, which furnishes the necessary support, and by taking suitable precautions a membrane may thus be obtained capable of withstanding a pressure of several atmospheres.

The behaviour of a solution when separated from pure solvent by such a semi-permeable membrane differs markedly from what takes place when an animal membrane is employed. In the latter case, at the outset water adds itself to the solution, the level of liquid and the pressure on the solution-side of the membrane thus rise until a maximum pressure-head is attained, which, roughly speaking, is greater the stronger the solution used. Seeing, however, that dissolved substance is continually escaping from the solution through the membrane, as soon as the maximum is reached the pressure-head begins to fall until eventually it vanishes, the levels of liquid on either side of the membrane being the same.

If, on the other hand, a semi-permeable membrane be employed, as before, a maximum pressure is attained, but since dissolved substance cannot leave the solution, this maximum pressure as well as the concentration of the solution remain constant.

When this constant state of things is established the excess of pressure on the solution-side of the membrane over that on the solvent-side, whatever it may mean, is termed the "osmotic pressure" of the solution. It is therefore customary to reserve the term *osmose* to phenomena relating to semi-permeable membranes, *diomose* being used in cases where, as with animal membranes, dissolved substance as well as solvent can traverse the membrane. It is obvious that when the pressure is established as indicated above, the original concentration of the solution has been altered by the entrance of solvent, and the observed osmotic pressure refers of course to the solution having the final concentration. If, however, we imagine the vessel containing the solution to be closed at the top, a quantity of air being imprisoned over the solution, pressure may be set up by compressing this air, only a small quantity of solvent being allowed to enter. If, further, the air enclosure be tapped by a manometer, measurements of the pressure may be taken, and by making the air enclosure and the volume of the manometer small enough the quantity of solvent entering while pressure is being established may be neglected, the original concentration of the solution remaining practically unaltered. This is the principle of the method employed in measuring osmotic pressure in absolute units.

The question now arises, "Are these measurements really independent of the nature of the membrane? Has the difficulty which beset the older experiments been overcome?" To this question an immediate answer is forthcoming, for, as pointed out by Prof Ostwald, it follows from theoretical considerations that if the membrane employed is really semi-permeable, the observed osmotic pressure of a given solution must be the same, no matter of what material the membrane is com-

posed. For suppose we have a quantity of solution enclosed in a tube, one end of the tube being closed by a membrane A, the other by a membrane B, and suppose it possible that a pressure  $P$  can be developed on the membrane A when it separates the solution from pure water, which is higher than the pressure  $p$  similarly developed when B separates the solution from pure water. On immersing the tube in water, the latter will begin to pass through both membranes into the solution. When the pressure  $p$  is attained passage through B will stop, but that through A will continue, but as soon as the pressure on the solution rises above  $p$ , water will be forced out through B. The pressure  $P$  will thus never be attained, water will continuously enter through A, and pass out at B. We will thus have a machine capable of doing an infinite amount of work, which is impossible. Similar reasoning shows that  $p$  cannot be greater than  $P$ , it follows therefore that the pressure developed on each membrane is the same, that the osmotic pressure must be independent of the nature of a truly semi-permeable membrane.

Actual observations are on record in which the osmotic pressure did appear to vary with the membrane employed. A sugar solution, for example, exhibited a much lower osmotic pressure with a membrane of Prussian blue or calcium phosphate than with copper ferrocyanide. From the preceding argument it is concluded, however, that these membranes giving the lower values were not quite firm or not quite impermeable to the dissolved substance; the highest value is thus taken as the measure of the osmotic pressure which is nearest the truth.

On glancing at the results which have been obtained, the first point which strikes one is the extraordinary magnitude of the pressures thus set up. In the case of a 1 per cent. aqueous solution of nitre the pressure attains the value of  $2\frac{1}{2}$  atmospheres. This value increases with the strength of the solution till at 3.3 per cent. it is no less than 6 atmospheres, this pressure being the highest which any membrane yet prepared has been able to withstand. With substances like sugar, other things being the same, the pressure is not so great, but in all cases, in order to keep it within workable limits, the solutions employed have to be dilute.

Striking as the results are themselves, their explanation is not less remarkable. The original measurements of osmotic pressure were made with the purpose of elucidating the movement of liquids in plant cells, and naturally the substances examined were such as occur in the vegetable organism—aqueous solutions of sugar, gum, dextrin, and the nitrate, sulphate, and tartrate of potassium. For some years after these observations were made, they lay comparatively unnoticed, until Prof. van't Hoff, of Amsterdam, turned them to a use undreamt of by their discoverer. From a study of the properties of dilute solutions van't Hoff came to the conclusion that the osmotic pressure was due to the bombardment of the molecules of the dissolved substance on the semi-permeable membrane. For when the osmotic pressure is established and equilibrium exists between solvent and solution, in the same time, equal amounts of solvent, must pass in either direction through the membrane and the impacts of the solvent molecules on the membrane will then be equal and opposed on either side, and therefore negligible. On this reasoning the pressure recorded on the manometer is taken to be that exerted by the substance in solution.

On examining the magnitude of the pressure thus attributed to the dissolved substance, in the case of a solution of sugar van't Hoff next showed that it bore the closest resemblance to the pressure of a gas. Indeed, if we calculate the pressure of a gas which at the same temperature contains as many molecules per unit volume as there are molecules of sugar per unit volume of solution, then the pressure of the gas and the osmotic pres-

sure are the same. Moreover, on thermodynamical grounds it was established that on the above hypothesis as to the nature of osmotic pressure its magnitude should be quantitatively connected with measurements of other physical properties of solutions, more especially those on the lowering of the vapour-pressure, and of the freezing point of a solvent produced by the presence of dissolved material. In this way a mass of evidence was collected, a general survey of which led to the foundation of the new theory of solutions. On this theory the dissolved substance, if the solution be dilute, is supposed to behave as if it were gaseous, the pressure it exerts—the osmotic pressure—being equal to the pressure which it would exert if it were gasified, and occupying, at the same temperature, a volume equal to the volume of the solution.

Unfortunately measurements of osmotic pressure have only been made on few substances, and only for solutions in water, but on turning to all the available observations to see how they support this novel conclusion, the most superficial examination serves to show that an agreement does not exist. Unless in the case of sugar, for no substance of known formula which has yet been investigated does the osmotic pressure agree with the corresponding gaseous pressure. These substances consist of salt solutions, and they invariably give higher osmotic pressures than theory demands. Similar disturbing influences have been observed when other physical properties of these solutions were measured, and to account for the facts an additional hypothesis has been put forward by Dr. Svante Arrhenius.

Salt solutions are electrolytes, they conduct the electric current, and undergo simultaneous chemical decomposition into their constituent ions. Experiment shows that such electrolytic solutions give high osmotic pressures, more particles appear to bombard the semi-permeable membrane than if the dissolved substance behaved as a gas. The new hypothesis states that this is really the case, the additional number of particles being produced from the breaking up of the dissolved substance. It states that in a solution which can be electrolyzed a portion at least of the dissolved substance exists already decomposed or dissociated into its ions, and that although these ions cannot be separated by diffusion they are so far independent that each can exercise an effect on the semi-permeable membrane.

The extent of this electrolytic dissociation is supposed to vary with the chemical nature of the dissolved substance, and to increase with the dilution. In very dilute solutions it may be complete, the whole of the dissolved substance being supposed to exist in the state of ions.

The second hypothesis gives, therefore, some explanation why the osmotic pressure of a salt solution is greater than that of a non-electrolytic solution of sugar, it further fixes the limits between which the osmotic pressure ought to vary in the case of an electrolyte, for the lower limit should be that of undissociated gas, the higher should be that of completely dissociated gas, each original molecule having decomposed into as many sub-molecules as there are ions in each molecule of salt.

So far as these limiting conditions go, the facts support the hypothesis. In all cases the observed osmotic pressure is either equal to one or other of the limits, or lies between them. A closer scrutiny leads, nevertheless, to apparent discrepancy. It is evident that a measure of the amount of dissociation can be obtained from osmotic pressure observations. For if we divide the observed osmotic pressure by the corresponding pressure of undissociated gas we have obviously, if the preceding hypotheses are valid, the ratio of the actual number of bombarding molecules to the theoretical number had no dissociation occurred. The ratio of these two numbers is denoted by the letter " $i$ ," a factor first used by van't Hoff. Now, on the new theory, the value of " $i$ " can be

obtained by measurements of other properties of salt solutions, the electric conductivity, the depression of the freezing point, &c., and the theory is compared with practice by seeing if the values of " $\pi$ ," as determined, say, from freezing point observations, agree with those deduced from the osmotic pressure. The comparison shows that in some cases, some half-a-dozen in all, the two sets of values correspond, in others, and in by far the majority, no such correspondences exist. In these latter instances it is argued, and with a certain amount of experimental evidence, that the salts were not without action on the membrane employed, and that, therefore, diosmose really took place, the membrane was not truly semi-permeable. In this way the discordant observations have been put out of court.

It is thus apparent that the leading hypotheses of the new theory do not receive confirmation of the weightiest kind from observations on osmotic pressure. Indeed, were they supported by such measurements alone, they would hardly be entertained. Their mainstay, however, lies in the mass of experimental work on many other properties—evidence which it is much easier to obtain than the difficult measurements on osmotic pressure—which has been correlated and explained by their use

been put forward in favour of the gaseous analogy. Several physicists, starting from entirely different points of view, have arrived at the result that in a dilute solution the dissolved substance should obey laws similar to those which hold for gases. At present the attitude of the prominent upholders of the new theory is one of indifference as to the exact mechanism of osmotic pressure. The numerical agreement between the measurements on solutions and those on gases is regarded as ample justification for considering dissolved substances to be in a *pseudo-gaseous* condition.

Whatever the ultimate explanation of the facts may be, there can be no doubt that the existing speculations on the nature of osmotic pressure and allied phenomena have infused new life into the study of solutions. Indeed, as instigators to fresh inquiry these hypotheses must take rank as the most fruitful of recent times.

J. W. RODGER

#### A SANITARIAN'S TRAVELS

MR ROBERT BOYLE has travelled round the world no fewer than four times for the purpose of studying sanitary science and preparing the way for the intro-

GREAT RECUMBENT FIGURE OF BUDDHA, PEGU, BURMAH

It is only fair to add that both hypotheses, from physical as well as chemical standpoints, have met with a measure of adverse criticism. The rôle played by the membrane has also been questioned. It has been suggested that it is not really semi-permeable, allowing solvent only to pass, but just as a porous plug behaves towards a mixture of gases, it allows molecules with different momenta to traverse it at different rates. Or, again, its action has been likened to that of a palladium film towards hydrogen, compounds being formed with the membrane substance on one side, these becoming diffused and dissociated on the other. If either of these views be correct the pressures exerted by dissolved substances have probably never been measured.

On the other hand, important theoretical support has

duction of the ventilating and sanitary appliances he has invented. An interesting account of his fourth journey is given in a little book entitled "A Sanitary Crusade through the East and Australasia," consisting of a series of papers reprinted from the *Building News*. In the course of this "crusade" Mr Boyle visited Burmah, the Malay native states, Sumatra, Siam, Borneo, Java, Australia, New Zealand, Samoa, the Sandwich Islands, and America. Of all the facts noted by him as a sanitarian the most remarkable are those relating to leprosy, a disease which he believes to be spreading to an alarming extent all over the world. He was particularly struck by the gigantic proportions the evil has assumed in Burmah. The steps of the great Shwedagon pagoda at Rangoon, the Mecca of the Indo-Chinese Buddhists, he found to be

"closely lined from top to bottom with lepers, suffering from that loathsome disease in its worst forms and most advanced stages." A number of the victims examined by Mr Boyle "presented a most sickening and awful spectacle." Yet no provision worthy of the name appears to be made for the maintenance or treatment of these poor lepers, who are thus compelled to resort to begging to keep themselves in existence. At Mandalay Mr Boyle came in contact with horrors of a similar nature. During times of high festival the entrances of the great Arakan pagoda in that city are crowded by hundreds of lepers, so that the visitor has to pick his way carefully among them. In the Sandwich Islands also Mr Boyle was strongly impressed by the terrible effects of the curse of leprosy, which, he says, has nearly decimated the native population.

He has a curious theory to the effect that the propagation of leprosy has been to a large extent connected with cannibalism, the disease "being spread wholesale through the eating of infected bodies." He has frequently seen in New Caledonia and the South Sea Islands human bodies "hanging up in the natives' huts, intended for future repasts, though then in an advanced stage of decomposition and exhaling a sickening odour."

The little book is by no means occupied only with these terrible subjects. Reference is made to many interesting things which came under Mr Boyle's observation in the course of his journey. We may especially note the impression produced upon him by Buddhist temples and various classes of objects associated with Buddhism in Burmah. Pagan, an ancient capital of Burmah, situated on the Irrawaddy between Mandalay and Rangoon, contains an enormous number of Buddhist temples of various sizes and styles of architecture, and the city, as seen from the river, is described by Mr Boyle as "one of the grandest and most impressive sights he has ever seen." Lower down the Irrawaddy below Prome there is a cliff about two miles long and 300 feet high, on the face of which are carved innumerable figures of Buddha ranged in tiers from the bottom to the top. He thinks that some of these figures cannot be less than twenty feet high. Many of them are richly gilded, and the whole forms "a very brilliant and curious sight." We reproduce an illustration showing the great recumbent figure of Buddha, in the province of Pegu, of which Mr Boyle reports that "it is said to measure about 270 feet in length by 70 feet at the shoulder." In a paper read lately before the Anthropological Institute (see *NATURE*, November 10, p. 46) Major R. C. Temple gives the length as 181 feet and the height at the shoulder as 46 feet. This remarkable monument is built of brick, and Major Temple speaks of it as "well proportioned throughout." It is supposed to have been produced in the fifteenth century. It was hidden from view by jungle until 1881, when it was accidentally discovered by a railway contractor.

#### GAUSS AND WEBER

IN bringing before our readers the contents of a circular we have received with respect to the erection of a monument, in Göttingen, to the two world-renowned scientific workers and friends, Charles Frederick Gauss and William Weber, we do so, knowing that every scientific man, whether he be astronomer, mathematician, or physicist, will be only too glad to have a chance of paying some tribute, however slight, to their memory.

Only about a year has gone by since the younger of the two, William Weber, passed away, having brought glory to the University of Göttingen, which was radiated throughout the whole scientific world. The work which both have done in the service of science cannot be said to be the property of their followers alone, but is a

precious heirloom of mankind, which has proved, and will continue to prove in the future, valuable in many ways in the service of technics, in methods of communication, and in civilization generally.

Gauss, who is almost unequalled among the scholars of the century, has not only left imposing landmarks of his great mind in all domains of pure mathematics, but he has also by his work furthered all departments of its applications in astronomy and physics, while his investigations have become standard for the theoretical as well as for the observational side.

What Gauss did for magnetism, Weber, whom Gauss had chosen for his fellow worker, attracted by his useful work on acoustics, did for the strength of galvanic currents, for their impelling electromotive forces, and for their resistances.

Further, in teaching how to measure these quantities in absolute units, he has furnished extremely important methods for their investigation. In this way not only has the science itself been furthered, but a firm basis for the development of electro-technics has been formed, the soundness of which is proved by its general adoption and which has contributed greatly to the tremendous advance witnessed during the last ten years. The pamphlet then goes on to say: "It is not the purpose of these lines to enlarge on the eminent works which we owe to the co-operation of these great investigators; we can only call to mind the fertile researches on the laws of the earth's magnetism, from which as it were a new branch of physics has developed; further, the attempts to encompass the phenomena of electrostatics, electrodynamics, and induction by one single law, attempts which, however a future generation may judge of them, will mark an important epoch in scientific development, and further, we may recall the most popular result of their co-operation, viz. the erection of the first telegraph practically adopted for communication at a distance."

Since the year 1877 the birthplace of Gauss has possessed a memorial of him, but Göttingen, the place where he and Weber worked, and where the former died, and which consequently became celebrated, possesses no such memorial. That this should be remedied is the object of this circular, and one has only to glance down the list of names attached to it—about 275 altogether—to see that it includes most of the learned men in Germany, and those of many distinguished foreigners. Among these we are glad to see the name of Lord Kelvin, President of the Royal Society.

The acting committee is composed of Prof Klein, E. v. Meier (Curator of the University), F. Merkel (Pro-rector of the University), G. Merkel (Over-burgomaster), Profs E. Riecke, E. Schering, W. Schur, W. Voigt, H. Weber, and S. Benfey (banker), and it is to the last mentioned that subscriptions should be addressed (S. Benfey, Bankgeschäft, Göttingen). The list will remain open until April 1, 1893.

#### THE ANNIVERSARY OF THE ROYAL SOCIETY

YESTERDAY being St. Andrew's Day the anniversary meeting of the Royal Society was held in their apartments at Burlington House. The auditors of the Treasurer's accounts having read their report, and the Secretary having read the list of Fellows elected and deceased since the last anniversary, the President (Lord Kelvin) proceeded to deliver the anniversary address. The medals were then presented as follows.—The Copley Medal to Prof Rudolf Virchow, For. Mem. R.S. (received by the Foreign Secretary), for his investigations in Pathology, Pathological Anatomy, and Prehis-

toric Archæology; the Rumford Medal to Mr Nils C. Dunér (received by the Swedish Minister), for his Spectroscopic Researches on Stars; a Royal Medal to Mr J. N. Langley, F.R.S., for his work on Secreting Glands, and on the Nervous System; a Royal Medal to the Reverend Prof. Pritchard, F.R.S., for his work on Photometry and Stellar Parallax, the Davy Medal to Prof. François Marie Raoult, of Grenoble, for his researches on the Freezing Points of Solutions, and on the Vapour Pressures of Solutions; and the Darwin Medal to Sir J. D. Hooker, F.R.S., on account of his important contributions to the progress of Systematic Botany, as evidenced by the "Genera Plantarum" and the "Flora Indica," but more especially on account of his intimate association with Mr Darwin in the studies preliminary to the "Origin of Species."

The Society next proceeded to elect the Officers and Council for the ensuing year. The following is a list of those elected.—President: The Lord Kelvin. Treasurer: Sir John Evans. Secretaries: Prof. Michael Foster, The Lord Rayleigh. Foreign Secretary: Sir Archibald Geikie. Other Members of the Council: Capt. William de Wiveleslie Abney, Sir Benjamin Baker, Prof. Isaac Bayley Balfour, William Thomas Blanford, Prof. George Carey Foster, Richard Tetley Glazebrook, Frederick Ducane Godman, John Hopkinson, Prof. Joseph Norman Lockyer, Prof. John Gray McKendrick, William Davidson Niven, William Henry Perkin, Rev. Prof. B. Price, The Marquis of Salisbury, Adam Sedgwick, Prof. William Augustus Tilden.

In the evening the Fellows and their friends dined together at the Whitehall Rooms, Hôtel Métropole.

The following is the address delivered at the anniversary meeting by Lord Kelvin—

Since our last Anniversary Meeting, the Royal Society has lost 27 Fellows on the Home list, and 5 Foreign Members, a sadly great number.

Pedro (Dom) II. (d'Alcantara), Emperor of Brazil, December 5, 1891.

Ramsay, Sir Andrew Crombie, December 9, 1891, aged 77.

Stas, Jean Servais, December 13, 1891, aged 78.

Bennett, Sir James Risdon, December 14, 1891, aged 82.

Devonshire, William Cavendish, 7th Duke of, December 21, 1891, aged 83.

Russell, William Henry Leighton, December 28, 1891, aged 68.

Kronecker, Leopold, December 29, 1891.

Wood, John, December 29, 1891, aged 66.

Airy, Sir George Biddell, January 2, 1892, aged 90.

Henry, William Charles, January 7, 1892, aged 88.

Quatrefages de Bréau, Jean Louis Armand de, January 12, 1892, aged 81.

Adams, John Couch, January 21, 1892, aged 72.

Paget, Sir George Edward, January 29, 1892, aged 83.

Calrd, Right Hon. Sir James, February 9, 1892, aged 76.

Dittmar, William, February 9, 1892, aged 59.

Grant (Lieut.-Col.), James Augustus, February 11, 1892, aged 65.

Hunt, Thomas Sterry, February 12, 1892, aged 66.

Bates, Henry Walter, February 16, 1892, aged 67.

Hunt, Thomas Archer, February 16, 1892, aged 61.

Kopp, Hermann Franz Moritz, February 20, 1892, aged 75.

Gregory, Right Hon. Sir William Henry, March 6, 1892, aged 75.

Knowles, Sir Francis Charles, March 19, 1892, aged 90.

Bowman, Sir William, Bart., March 29, 1892, aged 76.

Hofmann, August Wilhelm von, May 5, 1892, aged 74.

Thomson, James, May 8, 1892, aged 71.

Bramwell, George William Wilsher, Lord, May 9, 1892, aged 84.

Auker, Sir William, June 25, 1892, aged 67.

Schorlemmer, Carl, June 27, 1892, aged 58.

Clark, Frederick Le Gros, July 19, 1892, aged 82.

Sherbrooke, Robert Lowe, Viscount, July 27, 1892, aged 81.

Sutherland, George Granville William Sutherland-Leveson

Gower, Duke of, September 22, 1892, aged 64.

Tennyson, Alfred, Lord (Poet Laureate), October 6, 1892, aged 83.

Calver (Captain), Edward Killick, October 28, 1892.

Biographical notices will appear in the Proceedings.

During the past year, in the mathematical and physical section of the "Philosophical Transactions," eighteen papers have been published, and in the biological section, eleven, the two sections together containing a total of 1235 pages of letterpress and 50 plates. Of the "Proceedings," fourteen numbers have been issued, containing 1223 pages and 20 plates. This unusually large bulk is partly accounted for by the publication in the "Proceedings" of certain extra matters which the Council deemed likely to interest the Fellows. One part (No. 307), which forms an appendix to volume I, contains results of the Revision of the Statutes, to which I alluded in my Anniversary Address last year. It consists of a summary of the second and third chapters, and a copy of the Statutes as now revised, followed by an interesting note on the history of the Statutes, which has been drawn up by our senior secretary, Prof. Michael Foster. In addition to these matters, the same number contains a complete list of the portraits and busts at present in the apartments of the Society, compiled by order of the Library Committee, a work which was much needed, as no such list had been made since Weld's Catalogue, printed thirty-two years ago. The new "list" is not a descriptive catalogue, but the names of the painters and donors, and the dates of the gifts, so far as a thorough and somewhat laborious examination of the Council minutes and Journal books has revealed them, are furnished. The list of portraits is followed by a full descriptive catalogue of the medals at present in the possession of the Society, which has been carefully made by our clerk, Mr. James, under the supervision of the treasurer.

Another extra number of the "Proceedings" (No. 310) is devoted to a First Report of the Water Research Committee on the Present State of our Knowledge concerning the Bacteriology of Water, by Profs. Percy Frankland and Marshall Ward. It contains 96 pages, full of most valuable information regarding the vitality of micro-organisms in drinking water, to which in a large measure the spread of Asiatic cholera, typhoid fever, and other zymotic diseases is now known to be due.

In my Presidential Address of last year, I referred to this Water Committee as having been appointed by the Royal Society, in alliance with the London County Council, and this first instalment of its work seems amply to justify its originators in their expectations of results, most valuable for the public health, from the investigation which has been commenced.

A third extra number (No. 311) contains the report of the Committee on Colour Vision. This Committee, from the time of its appointment in March, 1890, held over thirty meetings, in course of which it examined more than 500 persons as to their colour vision, and tried various methods and many kinds of apparatus for colour testing. The report of the results of the whole inquiry contains a large mass of most interesting matter, and the Committee's work ends in a set of practical recommendations, from which we may hope that much benefit will come, in the prevention of inconvenience and disaster liable to be produced by mistake of colour signals, both at sea and on railways.

Mr. Ellis's communication (Roy. Soc. Proc., November, 1892, vol. II, p. 191) to the Royal Society of last May, and Prof. Grylls Adams' communication (Phil. Trans., vol. CXXXIII. 1891-92, p. 131) of June, 1891, both on the subject of simultaneous magnetic disturbances found by observations at magnetic observatories in different parts of the world; the award of a Royal medal two years ago to Herz, for his splendid experimental work on electro-magnetic waves and vibrations, and Prof. Schuster's communication (Phil. Trans. vol. CXXX. 1889, p. 467) to the Royal Society, of June, 1889, on the "Diurnal Variations of Terrestrial Magnetism," justify me in saying a few words on the present occasion regarding terrestrial magnetic storms, and the hypothesis that they are due to magnetic waves emanating from the sun.

Guided by Maxwell's "electro-magnetic theory of light," and the undulatory theory of propagation of magnetic force which it includes, we might hope to perfectly overcome a fifty years' out-

standing difficulty in the way of believing the sun to be the direct cause of magnetic storms in the earth, though hitherto every effort in this direction has been disappointing. This difficulty is clearly stated by Prof. W. G. Adams, in the following sentences, which I quote from his Report to the British Association of 1881 (p. 466) "On Magnetic Disturbances and Earth Currents" — "Thus we see that the magnetic changes which take place at various points of the earth's surface at the same instant are so large as to be quite comparable with the earth's total magnetic force, and in order that any cause may be a true and sufficient one, it must be capable of producing these changes rapidly."

The primary difficulty, in fact, is to imagine the sun a variable magnet or electro-magnet, powerful enough to produce at the earth's distance changes of magnetic force amounting, in extreme cases, to as much as  $\frac{1}{20}$ , or  $\frac{1}{30}$ , and frequently, in ordinary magnetic storms, to as much as  $\frac{1}{400}$  of the undisturbed terrestrial magnetic force.

The earth's distance from the sun is 228 times the sun's radius, and the cube of this number is about 12,000,000. Hence, if the sun were, as Gilbert found the earth to be, a globular magnet, and if it were of the same average intensity of magnetisation as the earth, we see, according to the known law of magnetic force at a distance, that the magnetic force due to the sun at the earth's distance from it, in any direction, would be only a twelve-millionth of the actual force of terrestrial magnetisation at any point of the earth's surface in a corresponding position relatively to the magnetic axis. Hence the sun must be a magnet of not much short of 12,000 times the average intensity of the terrestrial magnet (a not absolutely inconceivable supposition, as we shall presently see) to produce, by direct action simply as a magnet, any disturbance of terrestrial magnetic force sensible to the instruments of our magnetic observatories.

Considering probabilities and possibilities as to the history of the earth from its beginning to the present time, I find it unimaginable but that terrestrial magnetism is due to the greatness and the rotation of the earth. If it is true that terrestrial magnetism is a necessary consequence of the magnitude and the rotation of the earth, other bodies comparable in these qualities with the earth, and comparable also with the earth in respect to material and temperature, such as Venus and Mars, must be magnets comparable in strength with the terrestrial magnet, and they must have poles similar to the earth's north and south poles on the north and south sides of their equators, because their directions of rotation, as seen from the north side of the ecliptic, are the same as that of the earth. It seems probable, also, that the sun, because of its great mass and its rotation in the same direction as the earth's rotation, is a magnet with polarities on the north and south sides of its equator, similar to the terrestrial northern and southern magnetic polarities. As the sun's equatorial surface-velocity is nearly four and a half times the earth's, it seems probable that the average solar magnetic moment exceeds the terrestrial considerably more than according to the proportion of bulk. Absolutely ignorant as we are regarding the effect of cold solid rotating bodies such as the earth, or Mars, or Venus, or of hot fluid rotating bodies such as the sun, in straining the circumbient ether, we cannot say that the sun might not be 1000, or 10,000, or 100,000 times as intense a magnet as the earth. It is, therefore, a perfectly proper object for investigation to find whether there is, or is not, any disturbance of terrestrial magnetism, such as might be produced by a constant magnet in the sun's place with its magnetic axis coincident with the sun's axis of rotation. Neglecting for the present the seven degrees of obliquity of the sun's equator, and supposing the axis to be exactly perpendicular to the ecliptic, we have an exceedingly simple case of magnetic action to be considered: a magnetic force perpendicular to the ecliptic at every part of the earth's orbit and varying inversely as the cube of the earth's distance from the sun. The components of this force parallel and perpendicular to the earth's axis are, respectively, 0.92 and 0.4 of the whole, of which the former could only be perceived in virtue of the varying distance of the earth from the sun.

<sup>1</sup> The moon's apparent diameter being always nearly the same as the sun's, the statements of the last four sentences are applicable to the moon as well as to the sun, and are important in connection with speculation as to the cause of the lunar disturbance of terrestrial magnetism, discovered nearly fifty years ago by Krell and Sabine.

in the course of a year; while the latter would give rise to a daily variation, the same as would be observed if the red ends of terrestrial magnetic needles were attracted towards an ideal star of declination 0° and right ascension 270°. Hence, to discover the disturbances of terrestrial magnetism, if any there are, which are due to direct action of the sun as a magnet, the photographic curves of the three magnetic elements given by each observatory should be analysed for the simple harmonic constituent of annual period and the simple harmonic constituent of period equal to the sidereal day. We thus have two very simple problems, each of which may be treated with great ease separately by a much simplified application of the principles on which Schuster has treated his much more complex subject, according to Gauss' theory as to the external or internal origin of the disturbance, and Prof. Horace Lamb's investigation of electric currents induced in the interior of a globe by a varying external magnet. The sidereal diurnal constituent which forms the subject of the second of these simplified problems is smaller, but not much smaller, than the solar diurnal term which, with the solar semi-diurnal, the solar ter-diurnal, the solar quarter-diurnal constituents form the subjects of Schuster's paper. The conclusion at which he has arrived, that the source of the disturbance is external, is surely an ample reward for the great labour he has bestowed on the investigation hitherto, and I hope he may be induced to undertake the comparatively slight extension of his work which will be required for the separate treatment of the two problems of the sidereal diurnal and the solar annual constituents, and to answer for each the question:—Is the source external or internal?

But even though external be the answer found in each case, we must not from this alone assume that the cause is direct action of the sun as a magnet. The largeness of the solar semi-diurnal, ter-diurnal, and quarter-diurnal constituents found by the harmonic analysis, none of which could be explained by the direct action of the sun as a magnet, demonstrate relatively large action of some other external influence, possibly the electric currents in our atmosphere, which Schuster suggested as a probable cause. The cause, whatever it may be, for the semi-diurnal and higher constituents would also probably have a variation in the solar diurnal period on account of the difference of temperature of night and day, and a sidereal and annual period on account of the difference of temperature between winter and summer.

Even if, what does not seem very probable, we are to be led by the analysis to believe that magnetic force of the sun is directly perceptible here on the earth, we are quite certain that this steady force is vastly less in amount than the abruptly varying force which, from the time of my ancestor in the Presidential Chair, Sir Edward Sabine's discovery, forty years ago, of an apparent connection between sunspots and terrestrial magnetic storms, we have been almost compelled to attribute to disturbing action of some kind at the sun's surface.

As one of the first evidences of this belief, I may quote the following remarkable sentences from Lord Armstrong's Presidential Address to the British Association at Newcastle, in 1863:—

"The sympathy also which appears to exist between forces operating in the sun and magnetic forces belonging to the earth merits a continuance of that close attention which it has already received from the British Association, and of labours such as General Sabine has, with so much ability and effect, devoted to the elucidation of the subject. I may here notice that most remarkable phenomenon which was seen by independent observers at two different places, on September 1, 1859. A sudden outburst of light, far exceeding the brightness of the sun's surface, was seen to take place, and sweep like a drifting cloud over a portion of the solar face. This was attended with magnetic disturbances of unusual intensity, and with exhibitions of aurora of extraordinary brilliancy. The identical instant at which the effusion of light was observed was recorded by an abrupt and strongly-marked deflection in the self-registering instruments at Kew. The phenomenon as seen was probably only part of what actually took place, for the magnetic storm in the midst of which it occurred commenced before, and continued after the event. If conjecture be allowable in such a case, we may suppose that this remarkable event had some connection with the means by

<sup>2</sup> Communication to the Royal Society, March 18, 1859 (*Phil. Trans.*, vol. clxii. p. 143).

which the sun's heat is renovated. It is a reasonable supposition that the sun was at that time in the act of receiving a more than usual accession of new energy; and the theory which assigns the maintenance of its power to cosmical matter, plunging into it with that prodigious velocity which gravitation would impress upon it as it approached to actual contact with the solar orb, would afford an explanation of this sudden exhibition of intensified light, in harmony with the knowledge we have now attained, that arrested motion is represented by equivalent heat."

It has certainly been a very tempting hypothesis, that quantities of meteoric matter suddenly falling into the sun is the cause, or one of the causes, of those disturbances to which magnetic storms on the earth are due. We may, indeed, knowing that meteorites do fall into the earth, assume without doubt that much more of them fall, in the same time, into the sun. Astronomical reasons, however, led me long ago to conclude that their quantity annually, or per century, or per thousand years, is much too small to supply the energy given out by the sun in heat and light radiated through space, and led me to adopt unqualifiedly Helmholtz's theory, that work done by gravitation on the shrinking mass is the true source of the sun's heat, as given out at present, and has been so for several hundred thousand years, or several million years. It is just possible, however, that the outburst of brightness described by Lord Armstrong may have been due to an extraordinarily great and sudden falling in of meteoric matter, whether direct from extra-planetary space, or from orbital circulation round the sun. But it seems to me much more probable that it was due to a refreshed brightness produced over a larger area of the surface than usual by brilliantly incandescent fluid rushing up from below, to take the place of matter falling down from the surface, in consequence of being cooled in the regular régime of solar radiation. It seems, indeed, very improbable that meteors fall in at any time to the sun in sufficient quantity to produce dynamical disturbances at his surface at all comparable with the gigantic storms actually produced by hot fluid rushing up from below, and spreading out over the sun's surface.

But now let us consider for a moment the work which must be done at the sun to produce a terrestrial magnetic storm. Take, for example, the magnetic storm of June 25, 1885, of which Adams gives particulars in his paper of June, 1891 (*Phil. Trans.*, p. 139 and Pl. 9). We find at eleven places, St. Petersburg, Stonyhurst, Wilhelmshaven, Utrecht, Kew, Vienna, Lisbon, San Fernando, Colaba, Batavia, and Melbourne, the horizontal force increased largely from 2 to 2.10 p.m., and fell at all the places from 2.10 to 3 p.m., with some rough ups and downs in the interval. The storm lasted altogether from about noon to 8 p.m. At St. Petersburg, Stonyhurst, and Wilhelmshaven, the horizontal force was above par by 0.00075, 0.00088, and 0.00090 (C.G.S. in each case) at 2.10 p.m., and below par by 0.0007, 0.00066, 0.00075 at 3 o'clock. The mean value for all the eleven places was nearly 0.0005 above par at 2h. 10m., and 0.0005 below par at 3h. The photographic curves show changes of somewhat similar amounts following one another very irregularly, but with perfectly simultaneous correspondence at the eleven different stations, through the whole eight hours of the storm. To produce such changes as these by any possible dynamical action within the sun, or in his atmosphere, the agent must have worked at something like 160 million million million horse-power ( $1.6 \times 10^{18}$  ergs per sec.), which is about 364 times the total horse-power ( $3.3 \times 10^{17}$  ergs per sec.) of the solar radiation. Thus, in this eight hours of a not very severe magnetic storm, as much work must have been done by the sun in sending magnetic waves out in all directions through space as he actually does in four months of his regular heat and light. This result, it seems to me, is absolutely conclusive against the supposition that terrestrial magnetic storms are due to magnetic action of the sun, or to any kind of dynamical action taking place within the sun, or in connection with hurricanes in his atmosphere, or anywhere near the sun outside. It seems as if we may also be forced to conclude that the supposed connection between magnetic storms and sun-spots is unreal, and that the seeming agreement between the periods has been a mere coincidence.

We are certainly far from having any reasonable explanation of any of the magnetic phenomena of the earth, whether the fact that the earth is a magnet; that its magnetism changes vastly, as it does from century to century; that it has somewhat regular and periodic annual, solar diurnal, lunar diurnal, and

sidereal diurnal variations, and, (as marvellous as the secular variation) that it is subject to magnetic storms. The more marvellous, and, for the present inexplicable, all these subjects are, the more exciting becomes the pursuit of investigations which must, sooner or later, reward those who persevere in the work. We have at present two good and sure connections between magnetic storms and other phenomena: the aurora above, and the earth currents below, are certainly in full working sympathy with magnetostorms. In this respect the latter part of Mr. Ellis's paper is of special interest, and it is to be hoped that the Greenwich observations of earth currents will be brought thoroughly into relation with the theory of Schuster and Lamb, extended, as indeed Professor Schuster promised to extend it, to include not merely the periodic diurnal variations, but the irregular sudden changes of magnetic force taking place within any short time of a magnetic storm.

In my Presidential address of last year I referred to the action of the International Geodetic Union, on the motion of Prof. Foerster, of Berlin, to send an astronomical expedition to Honolulu for the purpose of making a twelve months' series of observations, on latitude, corresponding to twelve months' simultaneous observations to be made in European observatories, and I was enabled, through the kindness of Prof. Foerster, to announce as a preliminary result, derived from the first three months of the observations, that the latitude had increased during that time by  $\frac{1}{4}$  sec. at Berlin, and had decreased at Honolulu by almost exactly the same amount. The proposed year's observations, begun in Honolulu on June 1, 1891, were completed by Dr. Marcuse, and an elaborate reduction of them by the permanent Committee of the International Geodetic Union was published a month ago at Berlin. The results and in splendid agreement with those of the European observatories Berlin, Prag, and Strasbourg. They prove beyond all question that between May 1891 and June 1892 the latitude of each of the three European observatories was a maximum, and of Honolulu a minimum, in the beginning of October, 1891, that the latitude of the European observatories was a minimum, and of Honolulu a maximum, near the beginning of May, 1892, and that the variations during the year followed somewhat approximately, simple harmonic law as if for a period of 385 days, with range of about  $\frac{1}{2}$  sec. above and below the mean latitude in each case. This is just what would result from motion of the north and south polar ends of the earth's instantaneous axis of rotation, in circles on the earth's surface of 7.5 metres radius, at the rate of once round in 385 days.

Sometime previously it had been found by Mr. S. C. Chandler that the irregular variations of latitude which had been discovered in different observatories during the last fifteen years seemed to follow a period of about 427 days, instead of the 306 days given, by Peters' and Maxwell's dynamical theory, on the supposition of the earth being wholly a rigid body. And now, the German observations, although not giving so long a period as Chandler's, quite confirm the result that, whatever approximation to following a period there is, in the variations of latitude, it is a period largely exceeding the old estimate of 306 days.

Newcomb, in a letter which I received from him last December, gave, what seems to me to be, undoubtedly, the true explanation of this apparent discrepancy from dynamical theory, attributing it to elastic yielding of the earth as a whole. He added a suggestion, specially interesting to myself, that investigation of periodic variations of latitude may prove to be the best means of determining approximately the rigidity of the earth. As it is, we have now, for the first time, what seems to be a quite decisive demonstration of elastic yielding in the earth as a whole, under the influence of a deforming force, whether of centrifugal force round a varying axis, as in the present case, or of tide-generating influences of the sun and moon, with reference to which I first raised the question of elastic yielding of the earth's material many years ago.

The present year's great advance in geological dynamics forms the subject of a contribution by Newcomb to the Monthly Notices of the Royal Astronomical Society of last March. In a later paper, published in the *Astronomische Nachrichten*, he examines records of many observatories, both of Europe and America, from 1865 to the present time, and finds decisive evidence that from 1865 to 1890 the variations of latitude were much less than they have been during the past year, and seeming to show that an augmentation took place, somewhat suddenly, about the year 1890.

When we consider how much water falls on Europe and Asia

<sup>1</sup> 1 horse power =  $7.46 \times 10^8$  ergs per second.

how a careful observer in the British Islands may form a good judgment of the coming weather. The lecturer showed, with the aid of diagrams, the tracks followed by storm centres, with reference to the conditions of areas of low and high pressure. The reason why storms usually proceed in a north-easterly direction across or skirting these islands was explained as owing to the high barometer generally to be found in the Atlantic in the vicinity of the Azores, while in the neighbourhood of Iceland there is a region where the barometer is generally lower than in the space surrounding it. The storms generally advance so as to leave the low pressure on their left, and the high pressure on their right—moving round the south and east sides of the prevailing low pressure. Considerable stress was laid upon the importance of observing the cirrus clouds, the different motions of which, in conjunction with the indications of the barometer, are useful guides both as to the approach of a storm and the track along which the centre is moving. Several illustrations of these facts were given by the lecturer, who also gave many valuable hints as to what may be learnt from the published daily weather charts.

THE Leeds Naturalists' Club seems to be in no hurry about the publication of its Transactions, those for the year 1890 having only just been issued. The volume, however, has been prepared with great care, and shows that much good work is being done by the Club. Among the contents is a most interesting abstract of a lecture by the Rev. Edward Jones on relics found in Yorkshire caves. Reference was made to the cave at Kirkdale, near York, and the Victoria Cave of Settle, both of which have been well worked and have given valuable results, but attention was directed mainly to the cave found at Elbolton or Thorp, which is situated ten miles north of Skipton and two miles from Grassington. Through the energy of the president and members of the Skipton Natural History Society, this cave, which has been handed over to them, has been worked with great earnestness, and many bones have been turned up. Human remains, representing some thirteen bodies, have been found in an excellent state of preservation. These human beings must have been buried there, as they were all found in a sitting position, with the knees brought under the chin. The cave, however, was not used only as a burial-place, for the remains of charcoal fires, burnt bones, and pieces of pottery have been found. At the time when the lecture was delivered, the excavations had not revealed anything older than the Neolithic period. Among the finds are several specimens of bones of bears, red deer, foxes, dogs, badgers, grizzle and brown bears, &c. Some time after the delivery of the lecture the members of the Club made an excursion to this interesting cave, which was explored for a distance of a hundred feet, and to a vertical depth of thirty feet. The visitors saw many stalactites and stalagmites in course of formation, and the osseous remains of animals, including some now extinct. Mr. Jones pointed out the former location of several human skeletons.

MR. J. W. FOURNEY contributes to *Science* (November 11) an excellent paper on cliff and cave dwellings in Central Arizona. He refers especially to dwellings in cliffs rising a hundred feet or more above Beaver Creek, which flows into the Verde river. In the perpendicular walls of one of these cliffs is a well preserved ruin known as Montezuma's castle. It is midway between the rim of the cliff and the bed of the stream, and is neither house nor cave, but a combination of the two. Not accessible from the summit of the cliff, it can only be reached from below, and even here not without the use of a ladder, which, if short, the climber must pull up from one ledge to another in making the ascent. The entire front is of artificial walls built of large, flat pieces of limestone, with openings here and there for doors and windows. The rooms are small, only about five feet to the ceiling. Generally a small opening

two or three feet in diameter connects one room with another, and a small orifice in the ceiling gives access to the room above. The openings in the ceilings are never directly under one another, so that any one who might stumble could only fall the height of one story. The floors are mostly of flat stones supported on timber cut from the surrounding mountains. Many of the timbers are still sound. The rooms all show considerable skill in their construction. Those in the rear are dark, dungeon-like caves hollowed from the solid rock, and are now the abode of thousands of bats, which fly about in great numbers when disturbed by visitors. A few miles above Montezuma's castle, on the opposite bank of the creek, a conspicuous cone-like mountain rises a few hundred feet above the surrounding country. The summit is a narrow rim enclosing a crater some three hundred feet in diameter and with nearly perpendicular walls. Standing on the rim one can look down a hundred feet upon the dark-blue water of a small lake in the bosom of the mountain. The lake, a hundred yards in diameter and of unknown depth, is known as Montezuma's well. In the steep sides of the crater are a number of caves, which at one time were the abode of man. A few are natural, but the greater number are the result of human effort. The rim is crowned with the fallen walls of an ancient ruin more than a hundred feet long. Far down the mountain side, below the level of the water in the crater, the outlet of the well flows from between an opening in the rocks. This stream is large and constant, and at present is used to irrigate a ranch in the valley below. Ages ago the builders of caves and castles utilized this same stream to irrigate portions of the neighbouring rich valley.

THE fourth volume of "Reports from the Laboratory of the Royal College of Physicians, Edinburgh," edited by J. B. Tuke and D. Noel Paton, has just been published. The work completed in the Laboratory during the past year was so large that an account of the whole of it could not be included in the present volume.

A LARGE dirigible balloon is being constructed (*La Nature* informs us) at the military balloon works at Chalais-Mendon, under the direction of Commandant Renard. It will be similar in form to the *La France* of 1884-5, but longer, measuring about 230 feet in length and 43 feet in its greatest diameter. By a new arrangement of motor it is expected to be able to make headway against air currents not exceeding 40 feet per second (or 28 miles an hour). The motor is not fully described, but it will act either with gasoline or the gas of the balloon, giving an effective force of 45 horse-power on the shaft. The total weight of machinery, with supply of gasoline, &c., will be about 30 kilogrammes (or 66 lbs.) per horse power. Previously it has not been possible to make petroleum motors with a less weight than 150 to 200 kilogrammes per horse-power. The screw will be in front, and a large rudder behind, the former will make about 200 turns per minute. The first experiments with this balloon are to be made in the early spring.

DR. HEYDWEILER, of Wurzburg, has constructed a new mirror electrometer for high potentials (*Zeitschr. für Instr.*). It is a kind of torsion-balance with bifilar suspension, the charged bodies being a sphere and a ring. The attraction between the two, when at different potentials, is zero when the sphere is at the centre of the ring, and also when it is infinitely removed. Hence at some intermediate distance it is a maximum. In the instrument as constructed there are two spheres of 2 cm. diameter attached to the ends of a conducting bar bent in the form of an S. The combination is suspended in a horizontal plane by two brass wires 0.1 mm. thick attached to the middle of the bar. Two brass rings 10 cm. across are fixed in a vertical position such that the spheres can be made to coincide

with their centres. In the zero position the spheres are at a distance of 3 cm, this being a little less than the distance of maximum attraction. The deflections are indicated by those of a mirror carried by a thin glass rod attached to the curved arm below, and the motion is damped by a vane immersed in some vegetable oil. The tangents of the angle of deflection are proportional to the differences of potential to within 0.9 per cent., between the scale readings 0.05 and 0.4. The instrument is best adapted to potentials ranging from 6000 to 60,000 volts, but with potentials above 35,000 it is best to immerse it entirely in oil.

AN account of a series of experiments to determine the temperature of the flame of water-gas is given by Mr E. Blass, of Essen, in *Stahl und Eisen*. The instruments employed were Wyborgh's air pyrometer, Chatelier's electric pyrometer, Hartmann and Braun's telephonic pyrometer, and others by Siemens, Seeger, and Ducretel. It was found that Chatelier's formula for the variation of the specific heat of water vapour and other gases at high temperatures was practically reliable. The temperatures of combustion were taken for various proportions of air and gas, beginning with a large excess of the latter. With 0.18 cubic metres of air to one of gas, the temperature was 425° C. Calculated according to the old formula this would have been 521. Allowing for variation of specific heat, the theoretical value becomes 409. For 0.714 of air, the temperature was 1170, for 4.18 it was 1218, for 9.79 it was 655, and for the proportion of air just sufficient for combustion the flame temperature was 1169°.

A NEW "shortened telescope," constructed by Dr R. Steinheil, is described in the *Zeitschr für Instr* for November. The principle resembles that adopted by Dallmeyer and Dr A. Steinheil in their telephotographic objectives. A negative system is introduced between the object-glass and the eye piece, thus increasing its equivalent focal length. If  $a$  be the focal length of the objective by itself,  $r$  its distance from the negative lens, and the magnification  $m$  times that produced without the negative lens, the total length of the tube is given by  $l = r + m(a - r)$ . In a telescope actually constructed on this system, the object-glass had a focal length of 16.2 cm. Its distance from the nearest surface of the negative lens was 12 cm, the equivalent focal length 60.8 cm, and the total length 27.8 cm. Hence the magnification was 3.75 times that obtained by using the objective alone. In this case, then, a magnification of 22 diameters was obtained with an effective aperture of 4 cm, a total length of 27.8 cm, and a one inch eye piece. If the same magnification and illumination had to be obtained by a long-focus objective, the length would have to be 6.8 cm. Thus the length is reduced by more than one half without the usual disadvantages of short telescopes and eye-pieces of high power.

ACCORDING to a writer in the *Pioneer Mail* of Allahabad, the thatch on Burmese houses gives a tempting shelter to snakes, especially during the rains, and many of the occupants of the houses would be surprised if they knew the number of snakes that share the shelter of their roof on a rainy night. One night an officer was awakened up by a noise in his room, and by the light of a lighted wick, floating in a tumbler of oil, he made out that two combatants were disputing the possession of the small space in the centre of the bedroom. The belligerents turned out to be a snake and a rat, that somehow had jostled against each other in the tiny tenement.

A VALUABLE report on the geology of north-eastern Alabama and adjacent portions of Georgia and Tennessee, by C. Willard Hayes, has been published as a Bulletin of the U.S. Geological Survey. Mr. Hayes explains that in writing the

report he has tried to keep it as free as possible from technical terms, and, without sacrificing scientific accuracy, to present the facts in such a way as to make them intelligible to the largest possible number of readers in the region under consideration. Many details which would be of interest to the geologist have been purposely omitted, and only those which were considered essential are given. It is expected that the atlas sheets covering this region will shortly be published by the U.S. Geological Survey, and supply the details to those specially interested which are omitted from the report.

A SECOND edition of Prof. Oliver J. Lodge's "Modern Views of Electricity" has been published by Messrs Macmillan and Co. A new chapter on recent progress has been added.

A VOLUME on "The Pharmacy and Poison Laws of the United Kingdom" has been issued from the office of *The Chemist and Druggist*. It contains also a brief account of the pharmacy laws in force in Australasia, Canada, and Cape Colony.

MR CHARLES E. MUNROE, Torpedo Station, Newport, Rhode Island, U.S.A., has completed the manuscript of the second part of his index to the literature of explosives. The first part was issued in 1886. The second will be issued in pamphlet form if an adequate number of subscriptions is obtained.

MESSRS FRIEDLANDER AND SON, Berlin, send us the latest of their lists of the books which they offer for sale. It is a list of works relating to ornithology.

PENTA IODIDE and penta-bromide of cesium, together with several other penta-halogen compounds of the metals of the alkalis containing mixed halogens, have been isolated by Messrs Wells and Wheeler, and are described by them in the current number of the *Zeitschrift für Anorganische Chemie*. Cesium penta-iodide,  $\text{CsI}_5$ , is obtained in an impure form when the crystals of the tri-iodide of cesium,  $\text{CsI}_3$ , previously obtained by Prof. Wells and described in our note of February last, vol. xlv p. 325, is treated with hot water, or when solid iodine is treated with a hot solution of cesium iodide. Either of these processes produce it in the form of a black liquid, which solidifies in the neighbourhood of 73°. The tri-iodide of cesium, moreover, which is only sparingly soluble in alcohol, is found to be much more readily soluble when a quantity of iodine, corresponding to two atoms for each molecule of the tri-iodide, is added. Upon cooling, crystals of the penta-iodide of cesium are deposited. Remarkably well-formed crystals are obtained upon evaporation of a more dilute solution over oil of vitriol. The crystals are black and the faces extremely brilliant, they sometimes attain a diameter of a centimetre. They belong to the triclinic system according to Prof. Penfield, by whom they have been measured. They are at once distinguished from crystals of iodine by their form and brittleness. They melt at about 73°. When exposed to the air they lose iodine about as rapidly as crystals of free iodine. These crystals are anhydrous, and yield analytical numbers agreeing with the formula  $\text{CsI}_5$ . The penta-bromide of cesium may be similarly obtained by agitating a concentrated solution of cesium bromide with a large excess of bromine. When such a mixture is allowed to stand at a low temperature the excess of bromine slowly evaporates and the penta-bromide separates in the form of a dark red solid substance. Cesium penta-bromide  $\text{CsBr}_5$ , is a very unstable substance, losing bromine rapidly at the ordinary temperature. Another interesting compound is cesium tetrachloriodide,  $\text{CsCl}_4\text{I}$ , which was obtained by dissolving forty grams of cesium chloride in mixture of six hundred cubic centimetres of water and two hundred cubic centimetres of concentrated hydrochloric acid, adding

thirty grams of iodine, and then saturating the liquid with chlorine gas. The temperature was raised slightly during the operation, and upon subsequent cooling the compound  $\text{CsCl}_4\text{I}$  was deposited in the form of pale orange-coloured prismatic crystals belonging to the monoclinic system. The compound is only slightly soluble in water, but, with a little loss due to decomposition, may be recrystallized from that liquid. It is, however, quite stable in the air, and only decomposes upon heating, thereby producing the tri-halogen compound,  $\text{CsCl}_2\text{I}$ , fusing at  $238^\circ$ , the melting-point of this latter compound. A similar compound, containing rubidium instead of cesium,  $\text{RbCl}_4\text{I}$ , may be obtained in like manner in large orange-coloured tabular crystals, likewise belonging to the monoclinic system, but of different habitus to the crystals of the cesium compound. An analogous compound containing potassium,  $\text{KCl}_4\text{I}$ , was prepared so long ago as the year 1839, by Filhol. Messrs Wells and Wheeler finally describe sodium and lithium salts of this description, both of which, however, contain water of crystallization. They are represented by the formulæ  $\text{NaCl}_4\text{I} \cdot 2\text{H}_2\text{O}$  and  $\text{LiCl}_4\text{I} \cdot 4\text{H}_2\text{O}$ . Both crystallize well, the former in rhombic prisms, the latter, however, is so extremely deliquescent that measurements of the crystals have not been obtained.

THE additions to the Zoological Society's Gardens during the past week include two Common Marmosets (*Leontideus jacchus*) from South-east Brazil, presented by Mrs Comolli, an Otter (*Lutra vulgaris*) British, presented by Mr Frederick Collier, a Black-backed Jackal (*Canis mesomelas*, juv) from South Africa, presented by Miss Thornton, a Common Jackal (*Canis aureus*, ♀) from Fao, Persian Gulf, presented by Mr W D Cumming, C M Z S, two Short-headed Phalangiers (*Belides brevipes*, ♂ ♀) from Australia, presented by Capt S M Orr, a — Lemur (*Lemur* —) from Madagascar, six Crab eating Opossums (*Didelphys cauceriensis*), four Ypecha Rails (*Aramus ypecha*) from South America, a Green cheeked Amazon (*Chrysotis viridigenalis*) from Columbia, a Yellow-cheeked Amazon (*Chrysotis autumnalis*) from Honduras, purchased, a Nilotic Monitor (*Varanus niloticus*) from Africa, received in exchange, two Shaw's Gerbilles (*Gerbillus shawi*) born in the Gardens.

### OUR ASTRONOMICAL COLUMN.

COMET HOLMES (NOVEMBER 6, 1892).—The elements and ephemeris of this comet have been the subject of much computation during the present month. The first result obtained gave a place resembling in many particulars that of the long-sought for Biela comet, but owing to an error in one of the observations, the corrected elements stated otherwise. The current number of *Astronomische Nachrichten* (No 3129) gives four different systems of elements which have as yet been deduced, and it is quite worth while to produce them here, showing also the difference between the observed and reduced places for each in particular.

#### Elements, Berlin M T.

	1892	1892	1892	1892
T = Feb. 28 362	Mar 19 630	May 6 301	June 6 841	
$\omega$ =	340 25 82	339 11 87	334 46 90	328 19 09
$\Omega$ =	339 21 13	332 7 30	339 37 87	346 23 01
$i$ =	24 51 13	24 54 91	24 55 33	25 6 06
$\log g$ =	0 27766	0 26144	0 20868	0 14910
Mean place $\Delta\lambda$	-1 04	-0 81	-0 47	+0 50
(O - R) $\Delta\delta$	+0 86	+0 84	+0 38	+0 41

The latest information about the elements is that which has originated from Prof. Kreutz, who has found elliptic elements for the comet, he also says that the elements indicate that perturbations have taken place on account of the comet's proximity to the planet Jupiter. The elements are reduced from the three

places observed on November 9, 13, and 17, and are as follows —

Epoch 1892 Nov 17 5 M T Berlin.

$$\begin{aligned} M &= 22\ 18\ 37\ 1 \\ \omega &= 13\ 17\ 49\ 0 \\ \Omega &= 331\ 31\ 37 \\ i &= 20\ 54\ 8\ 1 \\ \phi &= 24\ 39\ 30\ 7 \\ \mu &= 500''\ 407 \\ \log \mu &= 0\ 567123 \\ U &= 7\ 09\ \text{years} \end{aligned} \quad 1892\ 0$$

Further observations of this comet are reported (*Comptes rendus*, No 21) At Algiers, MM Trépid, Ramlaud, and Sy found its position on November 15, at 8h 53m 41s. Algiers mean time, to be App R A oh 43m 22 28. App Decl +37° 43' 3" 9. The corresponding values found at Lyon by M. G Le Cadet at 8h 47m 33s, Paris mean time, were App R A oh 43m 22 72s App Decl +37° 43' 5" 9. The comet presented a bright nebulosity in the form of an elliptic segment with its axis directed in the position angle  $150^\circ$ , its length and breadth both being  $10''$ . The northern edge appeared rounded and well defined. At the focus of the ellipse a condensation could be distinguished, about  $20''$  broad, with a prolongation inclined to the axis of the ellipse. An attempt at calculating the elements of the orbit has been made by M. Schulhof. The slow motion of the comet renders this task very difficult. Among the various systems of elements tentatively fixed there is only one which fairly agrees with all observations. In this the eccentricity is as small as 0.355386, so that it will probably be possible to follow the comet throughout its orbit with the most powerful instruments. The other elements thus determined are  $\omega = 0^\circ 0' 39'' 1$ ,  $\Omega = 328^\circ 32' 40'' 7$ ,  $i = 20^\circ 26' 46'' 8$ , and  $\log g = 0.360966$ .

At Bordeaux, M F Courty succeeded in photographing the brighter portions of the comet on November 13, with one hour's exposure. Another photograph, taken by MM Paul and Prosper Henry at Paris, was presented to the Academy by M Tisserand. It was obtained on November 14, with the chart photographic equatorial. The exposure lasted two hours. It is a very fine photograph, showing a well defined and nearly circular contour. The nucleus is bright, eccentric and lengthened out. Several stars can be seen through it. There is no tail except the lengthening of the nucleus, which does not extend beyond the limits of the nebulosity.

A BRIGHT COMET.—A telegram from Kiel states that Mr W R Brooks has discovered a bright comet. As determined at Cambridge, U S, its place was, on November 21, at 16h 44m Cambridge M T.

R A 12h 59m. 15 68

Decl +13° 50' 27" 0

Daily motion  $\pm 1m\ 32s$ , and  $\pm 25''$  respectively

Another telegram, also from Kiel, gives the position, as obtained at Vienna on November 24, at 15h 49m. (Vienna M T), as

R A 13h 3m 6 41

Decl +15° 0' 36"

ASTRONOMICAL INSTRUMENTS UP TO DATE.—We have received a circular signed by Dr. L. Ambronn, of the Göttingen Observatory, and Herr Julius Springer, publisher in Berlin, setting forth the contents of a work which they propose to publish with regard to the general principles, constructions, and methods of using astronomical instruments in general. Such a book, of course, to be of the greatest value to science, must be completely done, but any one who is acquainted with the compiler and publisher mentioned above will be sure that each will do his share thoroughly and honestly. In constructing such a compendium of instruments as this is proposed to be, we might say it would be impossible for one man to do it alone, for the present state of the *ferment* has reached such a high pitch and the branches of astronomy are so numerous, that such an undertaking would simply be out of question. The object of this circular, besides stating the lines on which the work will be written, is to request the co-operation of all observatories. Astronomical science, especially the theoretical side, owes much, as we all know, to German workers, so that we can rely on a good response being given to this request. What is

asked is that descriptions, together with drawings or photographs not only of typical instruments but of the important parts of them, should be sent. Technical drawings also are requested, if obtainable, and these very probably could be obtained from the makers of the instruments in question. Of course it is not required that each observatory should send a description, &c., of the transit instrument there in use, but it is hoped that any instrument of peculiar construction or special merit should be referred to. It is needless to add that all drawings, &c., if requested, will be returned with as little delay as possible, and the undersigners of the circular thank in advance all those who respond towards the completion of this undertaking. The address to which the drawings, &c., may be sent is as follows—Dr L. Ambronn, Göttingen, Kgl. Sternwarte.

**MOTION OF  $\beta$  PERSEI.**—*Astronomical Journal*, No. 277, contains a short note calling the attention of transit observers to the importance of observation of this variable, to confirm the irregularity in its proper motion. At the present time Algol and his neighbouring stars are conveniently situated, and it is hoped that the following list of stars will be added to working lists generally where their observation is not inconsistent with other work. The places are for the year 1875—

	R. A.			Decl.	
	h	m	s		
$\gamma$ Andromedæ	1	56	14	41	43.7
$\beta$ Trianguli	2	2	7	34	23.7
$\theta$ Persei	2	35	40	48	41.9
$\delta$ Arietis	2	42	38	26	44.6
$\gamma$ Persei	2	55	45	51	0.9
$\phi$ Persei	2	57	10	38	21.3
$\beta$ Persei	3	0	2	40	28.3
$\alpha$ Persei	3	15	24	49	24.9
$\delta$ Persei	3	34	2	47	23.1
$\nu$ Persei	3	36	42	42	10.9
$\eta$ Tauri	3	40	3	21	43.0
$\zeta$ Persei	3	46	17	31	30.6
$\epsilon$ Persei	3	49	28	39	38.8
$\xi$ Persei	3	50	51	35	25.8

**PROPER MOTIONS.**—M. Deslandres, in *Comptes rendus* of November 14, communicates the recent work he has been carrying out with regard to the spectroscopic determinations of proper motions. The first part contains a description of the apparatus employed, showing how he has completely altered one instrument specially for this work. During the ten months of the year he has obtained several proofs of stars susceptible of furnishing radial velocity. The following are among some of the important methods of procedure:—(1) The luminous "faisceaux" of the star and of the source of light have the same aperture, and are thus as identical as possible, a condition necessary to the absolute measure of displacements. (2) The displacements of spectra is measured not only with the H $\gamma$  line of hydrogen, but with all the hydrogen, calcium, and iron lines. (3) The large surface of the mirror renders the possibility of measuring the velocities of 250 stars. Some of the results already obtained show that the work, when finished, will be of a very reliable and accurate kind. For instance, the velocity of Venus has been obtained instrumentally as 15 kilometers, while that calculated amounted to 13.55 km. The velocity of  $\alpha$  Auriga on February 5, employing 30 lines of comparison, came out as 43.5 km., and the velocities of the components of  $\beta$  Auriga, a spectroscopic double, were obtained on the same day as - 84.5 km. and + 97 km.

### GEOGRAPHICAL NOTES

THE measurement of an arc of the meridian between Dunkirk and the Spanish frontier, which has recently been completed with the highest precision by the French Government, shows that the measurement by Delamhere and Méchain in determining the length of the metre was 146.6 feet, or rather too short. The new measurement accords very closely indeed with the value as deduced from Clarke's ellipsoid.

A NEW weekly paper devoted to African geography, under the title of Kettler's *Afrikanische Nachrichten*, was started at Weimar in July last, with the object of collecting and publishing the most recent information on all matters connected with Africa and the Africans. An ingenious feature is that of giving a sketch map of parts of Africa, with a small section of a map of some well-known part of Germany on the

same scale below it, for the purpose of ready comparison of distances.

MR. AND MRS. THEODORE BENT have arranged to spend the winter in Abyssinia studying the ancient monuments of Axum. They will leave this country about the middle of December. We understand that Mr. Bent would welcome a scientific man who might wish to work at any of the natural conditions of eastern Abyssinia, and take advantage of the arrangements which have been made for the safety and comfort of the party. It would, of course, be necessary for such a companion to pay his own expenses and provide his own outfit.

A SPECIAL general meeting of the Royal Geographical Society was held on Monday afternoon to consider some alterations in the rules, recently decided on by the Council. It was agreed to raise the entrance fee to the Society from £3 to £5, and to augment the life composition accordingly, relief being, however, granted by a diminution of the commutation fee to members of long standing. Other changes were made to bring the laws into harmony with the present practice of the Society in several minor matters. The meeting also passed a resolution associating itself with the act of the Council in no longer withholding the Fellowship of the Society from women.

### MR JOSEPH THOMSON'S JOURNEY TO LAKE BANGWELO

MR JOSEPH THOMSON read a paper on his expedition to Lake Bangweolo in 1890-91 to the Royal Geographical meeting on Monday night. The paper was not only of a thoroughly scientific character, but also a model of literary grace, Mr. Thomson having the trained eye which enables him to detect and throw into prominence the really important features. The expedition went up the Zambesi by way of the Kwakwa creek, encountering considerable hostility and obstruction from the Portuguese authorities on the way. Mr. Thomson speaks warmly of the great work done by the Scottish missionaries in the Blantyre and Nyassa districts. Under the kind but firm control of the missionaries the warlike Angoni tribes came in thousands to cultivate the fields, which formerly they visited only for plunder, and for the first time in all his African travels Mr. Thomson found a spot where the advent of the white man was an unmitigated blessing to the natives.

Barometric observations made while waiting for porters on the western coast of Lake Nyassa made the elevation of the lake 1430 feet, a somewhat lower result than was formerly arrived at. On August 23, 1890, the expedition, comprising Mr. Grant, Mr. Charles Wilson, and 153 porters, started from Kotakota and struck westward through unmapped country, a rough and sparsely wooded plateau with little running water. The route lay along a strip of debatable ground, inhabited by an excitable, warlike tribe, and raided equally by Mwan's people from the north and Mpeseni's from the south. Great tact was required to avoid bloodshed, but the expedition passed safely. Then crossing the fine fertile plain of the Loangwa river, they passed over and climbed the steep Muchinga mountains to the high plateau beyond. So far the rocks had been metamorphic, with intruded masses of granite, overlaid in the valley by sandstones, shales, and marls. At one place great fossil-tree trunks were found. The Loangwa-Kafue plateau was magnificent country, glorious with the tints of early spring on the stunted trees which formed a scraggy forest over most of the surface. But no sign could be seen of the Lokanga mountains, nor was any word heard from the natives of that range so conspicuous on the maps, but on the watershed of the plateau, 5000 feet above the sea, rose the Vimbe hills in a series of isolated domes, perhaps rising 1000 feet higher. A new lake, thirty square miles in area, was found in a dip of the plateau, and named after the Moors. Then troubles began. Small-pox broke out amongst the porters, and when Chitambo's was reached no trace could be found of the lake, on the margin of which it was supposed to stand. While the white members of the expedition were attending to their sick followers some of the healthy Swahilis marched to Old Chitambo's (which is not in Ilala but Kalinde), now deserted, and twenty miles distant from the present village, finding the tree under which the heart of Livingstone was buried still standing, and the inscription on it legible. In the dry season the Chambesi does not enter Lake Bangweolo at all, but flows direct across the marsh to the Luapula, but in the wet season

the whole of the great marsh to the south is flooded up to Chitambo. The level at that time was made out to be 3750 feet, about 250 feet lower than Livingstone's estimate. After a rest for recovering health the expedition followed the Luapula eastward through fertile country, and leaving it where the curve from the north occurs, struck across for the Kafue, but small-pox reappeared, the land was ravaged by half caste Portuguese slave-raiders, Mr. Thomson himself fell ill, and the course had to be changed to the south with the hope of turning west again. But matters got worse instead of better, and after touching the borders of Manica, a return had to be made to Lake Nyassa, along the southern margin of the plateau, through deep valleys, and climbing the steep slopes of the Muchinga Mountains, here separated by the great parallel valley of the Lukosashu from the plateau. All the way the land was seen to be of immense possibilities for cultivation, but neglected, and inhabited by a wretched people governed by Mpesenti, himself the vilest of them all. Kotakota on the lake was reached again on January 4th, 1891, after a total journey of 1200 miles, which resulted in many important rectifications of position and much information as to the future possibilities of the plateaux.

### UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Dr. Hobson, late deputy Lowndean Professor, has been elected a representative of the Mathematical Board on the General Board of Studies.

Plans for a handsome building to serve as the Sedgwick Memorial Museum of Geology have been submitted to the Senate, the estimated cost being £26,000. Four members of the Syndicate appointed to prepare the plans dissent from the report of the majority, chiefly on the ground that the internal arrangements are unsatisfactory, and that the cost, initial and annual, of the proposed building will be excessive. The divergent views held on the subject will be discussed by the Senate on Saturday, December 3.

The Senate have agreed to confer on Sir R. S. Ball, the new Lowndean Professor, the complete degree of M.A., *honoris causa*.

### SOCIETIES AND ACADEMIES

#### LONDON

Physical Society, November 11.—Mr. Walter Baily, M.A., Vice-President, in the chair.—The discussion on Mr. Williams's paper, the dimensions of physical quantities, was resumed by Dr. Burton. He remarked that the idea that so called "specific quantities," such as specific gravity, are pure numbers was an erroneous one, and liable to lead to difficulties. The specific gravity of a substance was of the nature of density, and was only a simple number on the convention that the density of water was taken as unity. If dimensions be given to specific quantities their interpretation would, he thought, be easy when the rational dimensional formulæ were found. Referring to Prof. Fitzgerald's comments, he said, although the contention that all energy is ultimately kinetic could not be gainsaid, the distinction commonly drawn between kinetic and potential energy involved nothing contrary to this view, and was useful and convenient in many cases. As to the dimensions of  $\mu$  and  $k$  he was inclined to favour Mr. Williams's views, for several considerations suggest that the two capacities of the medium are essentially different. Arguments to show that  $\mu$  was probably absolutely constant in the ether, whilst  $k$  might be variable, were brought forward. Of the two systems of dimensions for  $\mu$  and  $k$  suggested by Mr. Williams, that which made  $\mu$  a density seemed preferable.—Prof. A. Lodge said he was greatly interested in propagating the idea that physical quantities are concrete, and therefore welcomed Mr. Williams's paper. He thought it desirable to keep some names for abstract numbers, and "specific gravity" should be one. If another name involving dimensions was required "specific weight," or "weight per unit volume," might be used. Speaking of the dimensions of the various terms of an equation he did not think it was usually recognized that in ordinary algebra or Cartesian geometry the principle of directed terms was rigidly adhered to, for if directed at all every term of such an equation was directed along the same line. In this respect ordinary algebra was more rigid than vector algebra. Even if circular

functions were involved, as in polar co-ordinates, they had the effect of making the directions of the terms the same. Other instances of problems bringing out the same fact were mentioned. Mr. Boys thought Mr. Madden had been arguing in a circle when he spoke of the astronomical unit of mass, and deduced the dimensions of mass as  $L^3/T^2$  from the equation  $MLT^{-2} = M^2/L^3$ , for it was quite impossible that this equation could be true unless  $\gamma$ , the gravitation constant, was introduced on the right-hand side. Mr. Williams's method was quite the reverse, for he maintained that unless  $k$  and  $\mu$  were introduced in the dimensions of electric and magnetic quantities, their dimensional formulæ could not indicate the true nature of those quantities, and hence were open to objection. Mr. W. Baily, whilst agreeing with Mr. Williams on most essential points, thought the total omission of  $L$  from dimensional formulæ made the expressions more complicated and less symmetrical. For example, such expressions as  $XV/Z$ ,  $X^2$  and  $XYZ$ , which respectively represent undirected length, area, and volume, might with advantage be written  $L$ ,  $L^2$ , and  $L^3$  respectively. The restriction of the dimensions of  $\mu$  and  $k$  to those which give interpretable dimensional formulæ for electrical and magnetic quantities seemed scarcely justified. Both the systems proposed could not be right, and he thought it would be more in accordance with our present want of knowledge, if a quantity  $U$  of unknown dimensions were introduced such that  $\mu$  or  $k = U^2$  density and  $k^{-1}$  or  $\mu^{-1} = U^2$  rigidity. This would keep in view the fact that the absolute dimensions of quantities involving  $U$  were unknown. A list of the dimensions of the various quantities based on this arrangement was given. Mr. Swinburne, referring to the conventional nature of many units, said great differences exist between the ideas held by different persons about such units. Starting with the convention that unlike quantities could be multiplied together, he might have six ampères flowing in an electric circuit under a pressure of ten volts, and he might say he had sixty volt-ampères. The term "volt ampère" could be regarded as indicating that the sixty was the numerical result of multiplying a number of volts by a number of ampères, or on the other hand it might be understood as a new unit, a *watt*, compounded of a volt and an ampère. Before Prof. Rucker's paper on suppressed dimensions was published, an electrician might have suggested measuring the length of a bench by sending an alternating current through it and determining its self induction, which he regarded as a length. Prof. Rucker, however, would say that this could not give the right result, for  $\mu$  must be taken into account. He was inclined to think that dimensions were liable to mislead. Referring to scientific writers as authorities, he said Maxwell had been careless in some cases, for he had sometimes given dimensional formulæ as zero, which really ought to have been  $L^3 M^{-1} T^{-2}$ , or unity. In French text-books the errors had been corrected. Mr. Williams, in reply to Mr. Madden's remarks about self-induction being a length, pointed out that the subject might be looked at in two different ways, depending on whether one thinks of the *standard* of self-induction as the practical standard of measurement, or the *unit* of self-induction as a physical quantity. In the former case the *standard* was a length, but in the latter the *unit* was a quantity of the same *species* as self-induction, the nature of which was as yet unknown. If its dynamical nature was known, then the absolute dimensions of all other magnetic and electric quantities would also be determined. In answer to Prof. Fitzgerald's remarks he said it was hardly likely that he should be unacquainted with the common view that kinetic and potential energies were ultimately quantities of the same kind, for it was a view with which he was quite familiar. The fact that they have the same dimensions was sufficient to show their identity, and the idea that all energy is ultimately kinetic was fundamental to his paper. This, however, did not imply that electrification and magnetization are of necessity the same, and the suggestion that they may be the same was only one of several "probable suggestions," all of which were entitled to consideration. His chief reason for regarding Prof. Fitzgerald's suggestion as probably incorrect was that it led to a system of dimensional formulæ incapable of rational mechanical interpretation, and containing fractional powers of the fundamental units. Prof. Fitzgerald's system would make resistance an abstract number, and  $\mu$  and  $k$  directed quantities, whereas the former was a concrete quantity and the two latter must be scalar in isotropic media. If he (Mr. Williams) had erred in treating electrification and magnetization as different phenomena he could only plead that he had

done nothing more than follow such authorities as Lord Kelvin, Dr Lodge, and Mr O Heaviside in the matter.—The discussion on Mr Sutherland's paper, on the laws of molecular force, was reopened by Prof Perry reading a communication from the President, Prof Fitzgerald. He objected to discontinuous theories, especially when Clausius had given a continuous formulæ much more accurate over a very long range than Mr Sutherland's discontinuous ones. The introduction of Brownian motions without carefully estimating the rates required and energy represented, and without giving any dynamical explanation of their existence, was not satisfactory. It would, he said, be most interesting if Mr Sutherland would calculate the law of variation of temperature with height of a column of convectionless gas, under conduction alone (for Maxwell thought the inverse fifth power law of molecular attraction was the only one that gave uniformity of temperature under these conditions), and if necessary make tests with solid bars. Referring to the statement that molecular attraction at one cm was comparable with gravitation at the same distance, he thought Mr Boys would question this, and he suggested an *experimentum crucis* of the inverse fourth power law. Both the inverse fourth and inverse fifth power laws, assumed symmetry which did not exist. He also took exception to other parts of the paper. Dr Gladstone, referring to the relative dynic and refraction equivalents given in Table XXVIII of the paper, said he thought it interesting to make a similar comparison between dynic and dispersion and magnetic rotation equivalents. The result as exhibited in a complete table showed a certain proportionality between the four columns but the differences were beyond the limits of experimental error. Mr Sutherland, however, sometimes reckoned the dynic equivalent of hydrogen as 0.215, and at other times looked upon it as negligible. The analogies between the optical equivalents did not depend on the proportionality of the numbers so much as upon the fact that the refraction, dispersion, and magnetic rotation equivalents of a compound was the sum of the corresponding equivalents of its constituent atoms, modified to some extent by the way in which they were combined. Whilst a somewhat similar relation held true for the dynic equivalents, the effect of "double linking" of carbon atoms, so evident in the optical properties, was scarcely perceptible. The result of calculating the constants from  $M^1$  instead of from  $M^2$  was next discussed, the effect of which was to quite upset the proportionality before noticeable. Mr S H Burbury said that on referring to the author's original paper, on which the present one was based, he found that a uniform distribution of molecules was assumed. On this supposition the demonstrations given were quite correct, and the potential was a maximum. If, however, the molecules were in motion the average potential must be less than the maximum, and the deductions in the present paper being based on wrong assumptions were liable to error. Prof Ramsay remarked that many statements in the paper, on the subject of critical points, were very doubtful. Separate equations for the different states of matter were not satisfactory, neither was the artificial division of substance into five classes. The predicted differences in the critical points due to capillarity, had not been found to exist. Speaking of the virial equation, he said that hitherto  $R$  had been taken as constant. Considerations he had recently made led him to believe that  $R$  was not constant. The whole question should be reconsidered regarding  $R$  as a variable. Mr Macfarlane Gray said he had been working at subjects similar to those dealt with in Mr Sutherland's paper, but from an opposite point of view, no attraction being supposed to exist between molecules. In the theoretical treatment of steam he found that no arbitrary constants were required, for all could be determined thermo-dynamically. The calculated results were in perfect accord with M Cailletet's exhaustive experiments except at very high pressures, and even here, the theoretical volume was the mean between those obtained experimentally by Cailletet and Battelli respectively. Prof. Henschel pointed out that Villard had discussed the equation of the virial, where the chemical and mechanical energies were not supposed to balance each other. Mr. Sutherland's paper all turns on the existence of such a balance, and he (Prof. Henschel) could not understand why this balancing was necessary. The discussion was then closed, and the meeting adjourned.

Geological Society, November 9.—W H. Hudleston, F.R.S., President, in the chair.—The following communications were read:—A sketch of the geology of the iron, gold, and copper districts of Michigan, by Prof M. E. Wadsworth.

After an enumeration of the divisions of the azoic and palæozoic systems of the upper and lower peninsulas of Michigan, the author describes the mechanically and chemically formed azoic rocks, and those produced by igneous agency, adding a table which shows his scheme of classification of rocks, and explaining it. The divisions of the azoic system are then described in order, beginning with the oldest—the cascade formation, which consists of gneissose granites or gneisses, basic eruptives and schists, jaspilites and associated iron ores, and granites. The rock of the succeeding republic formation are given as nearly as possible in the order of their ages, commencing with the oldest—Conglomerate, breccia and conglomeratic schist, quartzite, dolomite, jaspilite and associated iron ores, argillite and schist, granite and felsite, diabase, diorite and porodite, and porphyrite. The author gives a full account of the character, composition, and mode of occurrence of jaspilite, and discusses the origin of this rock and its associated ores, which he at one time considered eruptive, but new evidence discovered by the State Survey and the United States Survey leads him to believe that he will have to abandon that view entirely. In the newest azoic formation, the Holyoke formation, the following rocks are met with—Conglomerate, breccia and conglomeratic schist, quartzite, dolomite, argillite, greywacke and schist, granite and felsite (?), diabase, diorite, porodite, peridotite, serpentine, and melaphyre or picrite. The conglomerates of the Holyoke formation contain numerous pebbles of the jaspilites of the underlying republic formation, a description of the Holyoke rocks is given, and special points in connexion with them are discussed. The author next treats of the chemical deposits of the azoic system, gives a provisional scheme of classification of ores, and discusses the origin of ore deposits. The rocks of the palæozoic system are next described, and it is maintained that the eastern sandstone of lower silurian age underlies the copper-bearing or Keweenaw rocks. The veins and copper deposits are described in detail, and the paper concludes with some miscellaneous analyses and descriptions, as well as a list of minerals found in Michigan. After the reading of this paper, the President noted that it presented three sets of questions of much importance, viz., those bearing on the archæan rocks, the iron deposits and jaspilites, and the copper and gold deposits respectively. As regards the classification of the archæan rocks, some might wonder what the terms used by the author meant. The words laurentian and huronian used in Canada seemed not to be tolerated in Michigan. The officers of the United States Geological Survey have described all the archæan formations noticed by the author, the cascade as the fundamental complex, the republic as the lower marquette, and the Holyoke as the upper marquette. Was each State of the Union going to divide these archæan rocks after its own fashion? With regard to the iron rocks, he would observe that the author, after enumerating all the views in favour of their volcanic origin, now admitted that he was wrong, and that Irving and others were correct. The most important question was how the iron ores were really formed, and to this it was difficult to find a complete answer in the paper. Sir Archibald Geikie remarked that it was hardly possible to criticize a voluminous paper of this nature, in the reading of which much of the detailed statement of facts was necessarily omitted. One of its most interesting points related to the nature and classification of the rocks intermediate between the base of the Cambrian system and the oldest or fundamental gneisses. The plan which Prof. Wadsworth followed of adopting local names for the several subdivisions of the series in each region was no doubt in the meantime of advantage, until some method of correlation and identification from region to region could be discovered. But it unavoidably led to temporary confusion, for the same rock group might turn out to have received many different names. He thought it would be of service if geologists could agree upon some general term which would denote the whole of the sedimentary groups or systems which intervene between the old gneisses and the *Olenellus*-zone. Various names had been proposed, such as azoic, eoazoic, proterozoic, algonkian, to each of which some objection may be raised. The existence of a number of very thick systems of sedimentary deposits between the base of the Cambrian formation and the gneisses was now well established in this country and in North America. In the upper members of this series fossils had been found, and it might eventually be possible to group the rocks by means of palæontological evidence. But in the meantime it would be convenient to class them under one general name which would clearly mark them off from the true archæan gneisses, &c., below them and the palæozoic rocks

above Dr Hicks congratulated Prof. Wadsworth on his important communication, but he strongly objected to the application of the term Silurian, instead of Cambrian, to the lower palæozoic rocks of America. Dr Hicks did not think that the author had proved his case with regard to the Keweenaw rocks, and he was still inclined to believe that they would prove to be, as suggested by other American geologists, of pre-Cambrian age—the apparent superposition being due to over-thrust faults. The term eo-zoic, now that worm tracks have been discovered in the pre Cambrian rocks, is more correct than azoic for the sedimentary rocks of that age. Moreover, other organic remains will certainly be found, for it is inconceivable that ancestors of the forms comprising the rich fauna at the base of the Cambrian should not have been entombed in earlier rocks. Mr H. Baerman, considering the three hypotheses as to the origin of the iron ores—namely, dehydration of limonites in sandy beds, transformation from siderite, and the breaking-up of highly ferri-ferrous igneous masses into quartz and hematite—thought that the first was the most likely, although there were certainly difficulties in connexion with it which made it desirable that the newer views upon the subject should be presented. He was therefore glad that they were likely to have a detailed exposition of the author's views in the journal. As regards the origin of the copper deposits, he believed that Dr Wadsworth agreed with the views brought before the society several years since. In conclusion, he called attention to the gold deposits, which were of comparatively recent discovery, and interesting from the large number of minerals associated with the auriferous quartz vein-stuff. Sir Lowthian Bell and Mr Marr also spoke.—The gold quartz deposits of Pahang (Malay Peninsula), by H. M. Becher.—The Pambula gold deposits, by F. D. Power.

Zoological Society, November 15.—Dr A. Gunther, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of October 1892, and called special attention to a very fine male Ostrich (*Struthio camelus*) presented by Her Majesty the Queen, and to a specimen of what appeared to be a new and undescribed Monkey of the genus *Cercopithecus*, obtained by Dr Moloney at Chindi, on the Lower Zambesi, for which the name *Cercopithecus stans* was proposed. Attention was also called to the receipt of a series of specimens of mammals, birds, and reptiles, brought by Mr. Frank Finn, on his recent return from a zoological expedition to Zanzibar, and received from several correspondents of the Society at Zanzibar and Mombasa.—The Secretary exhibited (on behalf of Mr. T. Ground) a specimen of the Siberian Pectoral Sandpiper (*Tringa acuminata*) killed in Norfolk.—Mr G. A. Boulenger read a paper describing the remains of an extinct gigantic tortoise from Madagascar (*Testudo grandidiersi*, Vail.), based on specimens obtained in caves in South-west Madagascar by Mr. Last, and transmitted to the British Museum. The species was stated to be most nearly allied to *Testudo gigantea* of the Aldabra Islands.—Mr W. Bateson and Mr H. H. Brindley read a paper giving the statistical results of measurements of the horns of certain beetles and of the forceps of the male earwig. It appeared that in some of these cases the males form two groups, "high" and "low", the moderately high and the moderately low being more frequent than the mean form in the same locality. It was pointed out that this result was not consistent with the hypothesis of fortuitous variation about one mean form.—A communication was read from Mr. O. Thomas containing the description of a new monkey of the genus *Semnopithecus* from Northern Borneo, which he proposed to call *S. everetti* after Mr A. Everett, its discoverer.—Mr G. A. Boulenger read a description of a Bleanoid fish from Kamtschatka belonging to a new generic form, and proposed to be called *Alennoptichium petropauli*. The specimen had been obtained in the harbour of Petropaulovski by Sir George Baden Powell, M.P., in September 1891.

Royal Meteorological Society, November 16.—Mr A. Brewin, Vice-President, in the chair.—An interesting paper by Mr. J. Lovel was read on the thunderstorm, cloudburst, and flood at Langtoft, East Yorkshire, July 3, 1892. The author gives an account of the thunderstorm as experienced at Driffield on the evening of this day, the full force of the storm was, however, felt in the wold valleys, which lie to the north and north-west of Driffield, where great quantities of soil and gravel were removed from the hill-sides and carried to the lower districts, doing a large amount of damage. Many houses in the lower parts of Driffield were flooded, and a bridge considerably

injured. The storm was most severe in a basin of valleys close to the village of Langtoft, where three trenches, sixty-eight yards in length and of great width and depth, were scooped out of the solid rock by the force of the water from the cloudburst. From the appearance of the trenches it is probable that there were three waterspouts moving abreast simultaneously. This particular locality seems to be favourable for the formation of cloudbursts, as there are records of great floods having previously occurred at Langtoft, notably on April 10, 1657, June, 1857, and June 9, 1888. The author gives, in an appendix, a number of observations made on similar occurrences, together with particulars and opinions as to the cause of such outbursts by several eminent authorities.—Mr W. H. Dines also read a paper, remarks on the measurement of the maximum wind pressure, and description of a new instrument for indicating and recording the maximum. For some years the author has been conducting a large number of experiments with various forms of anemometer, and in the early part of the present year recommended the adoption of the tube anemometer for general use, as it appeared to possess numerous advantages. The head is simple in construction, and so strong that it is practically indestructible by the most violent hurricane. The recording apparatus can be placed at any reasonable distance from the head, and the connecting pipes may go round several sharp corners without harm. The power is conveyed from the head without loss by friction, and hence the instrument may be made sensitive to very low velocities without impairing its ability to resist the most severe gale. In the present paper the author describes an arrangement of this form of anemometer which he has devised for indicating very light winds as well as recording the maximum wind pressure.

Linnean Society, November 17.—Prof. Stewart, President, in the chair.—The President having announced a proposal by the council to present a congratulatory address to the Rev. Leonard Blomefield (formerly Jenyns) on the occasion of the seventieth anniversary of his election as a Fellow of the Society, and in recognition of his continuous and useful labours as a zoologist, it was moved by Sir Wm. Flower and seconded by Dr St. George Mivart, that the address be signed and forwarded as proposed. This was carried unanimously. In moving the resolution, Sir Wm. Flower took occasion to sketch the scientific career of Mr. Blomefield, who is now in his ninety-third year, and to recapitulate the works of which he is the author under his earlier and better known name of Jenyns. The address, which was beautifully illuminated on vellum, was then signed by those present.—Mr. George Murray exhibited and made remarks upon a genus of Algae (*Halcythus*) new to Britain, the species shown being *H. ventricosa* from the West Indies, and *H. ovalis* from the Clyde Sea area.—Mr. Buxton Shillitoe exhibited an artificial cluster of the fruit of *Pyrus sorbus*, as put up for ripening by cultivators in Sussex.—A paper was then read by the Rev. Prof. Henslow on a theoretical origin of endogenous organs. The lecture, which was very fluently delivered, was profusely illustrated, and drew forth some interesting criticism from Prof. Boulenger, Messrs. Henry Groves, H. Goss, and Patrick Geddes, to which Prof. Henslow replied.—On behalf of Mr. George Lewes, who was unable to be present, a paper was read by Mr. W. Percy Sladen on the *Suprasteria* of Japan, upon which some criticism was offered by Mr. W. F. Kirby.

Royal Microscopical Society, November 16.—Dr. R. Braithwaite in the chair.—Mr. T. F. Smith read a note on the character of markings on the *Podura* scale.—An account of Mr. W. Went's paper on the freshwater algae of the English lake district was given by Mr. A. W. Bennett, who thought it was an exceedingly important contribution to our knowledge of the algae of that district.—Mr. F. Chapman gave a résumé of Pt. 3 of his description of the foraminifera of the Gault of Flikestone.—Mr. C. Haughton Gill read a paper on a fungus internally parasitic in certain diatoms, illustrating his subject with specimens and photomicrographs. Mr. Bennett said that he had observed structures which might be of a similar character in diatoms. He should like to enquire if by the term "spores" Mr. Gill did not mean zoospores? Had he observed them to be possessed of vibratile cilia? And could he form any idea as to how they came to be inside the diatoms? It was possible that they might be transmitted in some way by inheritance, and if so that might account for their great abundance in particular species. Mr. Gill said

that the question how these things got into diatoms was one still under consideration. As to the movements of the spores he was not at present perfectly certain that they moved at all more than a very short distance from the orifice of the beak, but he had not yet had time to examine them sufficiently to be able to answer the question as to whether they were ciliated. Diatoms were by no means the tightly shut-up boxes which they were supposed to be; they could not live or absorb nutriment unless there was some sort of passage, and he thought there was very likely a means of penetration all over them to admit of the diffusion of fluid throughout. — Mr E. M. Nelson called attention to the fine adjustment of Messrs W. Watson's Van Heurck microscope, which he said had been wrongly described as being on Zentmayer's plan, he found that Messrs Watson's adjustment was provided with spring stops, which obviated all the evils complained of in Zentmayer's system, the adjustment-screw was also left-handed, so that the apparent and real motions were made to coincide, which was a great advantage when working with high powers.

## OXFORD.

University Junior Scientific Club, November 9. — The President, Dr J. Lorrain Smith, in the chair. — The President gave an exhibit to illustrate the relation of ventilation to respiratory products, after which he called on the Rev F. J. Smith for his paper on the inductoscript and spark photography. The paper, which was illustrated with experiments, and a large and varied selection of lantern slides, dealt with the recent researches of the writer and others in an exhaustive manner. It was shown how impressions of coins, &c., could be taken on photographic plates and paper by means of the electric spark, and the various results produced by changes of pressure, &c., in the atmosphere. The second part of the paper dealt more with the instantaneous photography produced by the electric spark, and the exhibits included photographs of bullets and other rapidly-moving objects, which had been taken by the reader of the paper. — Mr G. C. Burne read a paper on Büschli's researches on protoplasm, which was followed by an animated discussion in which Prof. Burdon-Sanderson and others took part.

## CAMBRIDGE

Philosophical Society, November 14. — Prof T. McKenny Hughes, President, in the chair. — The President exhibited (1) a live tarantula, (2) quartz crystals of unusual form. The following communications were made. — (1) Preparations were exhibited showing the division of nuclei in the sporangium of a species of *Trichia*, one of the Myxomycetes. The nuclei divide throughout the sporangium, with clearly recognizable karyokinetic figures, immediately before the formation of the spores, by J. J. Lister. — (2) On the reproduction of *Orbitolites*. Mr. H. B. Brady has described specimens of *Orbitolites*, which he obtained in Fiji, showing the margin of the disc crowded with young shells. Mr Brady's material was worked at in the dry state, and it was at his suggestion that the author collected specimens preserved in spirit from the Tonga reefs. Examination of this material shows that large brood chambers are formed at the margin of the disc during the later stages of growth. These are at first lined with a thin layer of protoplasm. At a later stage the central region of the disc is found to be empty, and the whole of the protoplasm is massed in the brood chambers in the form of spores. The spores have the structure of the "primitive disc," which during the early stages of growth of the *Orbitolites* occupies the centre of the shells. They are liberated by absorption of the walls of the brood chambers, and each becomes the centre of a new disc, which is built up by additions of successive rings of chamberlets at the margin. The reproduction of *Orbitolites* therefore takes place by spore formation. The spore contains a single nucleus, lying in its "primordial chamber." After several rings of chamberlets have been added, a stage is reached at which the nucleus appears to be represented by numbers of irregular, darkly staining masses scattered through the protoplasm of the central part of the disc. In the later stages numbers of oval nuclei are found in the protoplasm, often arranged in pairs, and in favourable preparations they may be seen to be undergoing amitotic division. — The fragmentation of the upper nucleus in certain ova, by S. J. Hixson. — On Gynodreemism in the Labiatae (second paper), by J. C. Willis. — The observations made in 1890-91 on *Organism* (see *Reporter*, No. 937, June 7, 1892) were continued, chiefly on female plants. Six of these, derived from seed of the hermaphrodite plants of 1890, were observed, and their variations noted. It

seems possible that some of the six, at any rate, were derived not from the normal, but from the abnormal (female) flowers of the parent. Attempts were made to determine if the occurrence of female flowers or flowers with one, two or three stamens only, on hermaphrodite plants, was due to lack of nourishment. A string was tied tightly round the main stalk of an inflorescence, about the middle, and it was found that more variations (12:1) occurred above than below. Analysis of the three years' observations shows that the abortion of the stamens tends to occur symmetrically rather than not, i.e. most commonly all four abort, and next in frequency is the abortion of the two anteriors then of the two posteriors. These observations are still in progress, and it is hoped to publish full details in 1896 or later.

## PARIS

Academy of Sciences, November 21. — M. d'Abbadie in the chair. — Observations of the minor planets, made with the great meridian instrument of the Paris Observatory, from October 1, 1891, to June 30, 1892, by M. Tisserand. — Determination of the centre of the mean distances of the centres of curvature of the successive developments of any plane line, by M. Haton de la Goupillière. — Observations of Holmes' comet (November 6, 1892) made at the great equatorial of the Bordeaux Observatory, by M. G. Rayet. — Exploration of the higher regions of the atmosphere by means of free balloons provided with automatic recorders, by M. Gustave Hermite. Small balloons were filled with coal gas and provided with recording barometers and minimum thermometers. The former consisted of metallic aneroid boxes on Vidi's system, recording the pressure by the motion of a smoked plate in front of a glass style. These aneroids weighed less than 100 grs. The writer hopes to reduce their weight to 10 grs. Some of the balloons were lost or destroyed, but most of them were returned, after a journey exceeding in many cases 100 km. Two successful registrations of temperature have been made so far, giving a fall of 1° C. for every 260 m. and 280 m. respectively. — Observations of Holmes' comet made at the Algiers Observatory (*equatorial cond.*), by MM. Trepiéd, Raubaud, and Sy. — Observations of Holmes' comet (November 6) made with the *equatorial cond.* of the Lyon Observatory, by M. G. Le Cadet. — Elliptic elements of Holmes' comet of November 6, 1892, by M. Schulhof (see our *Astronomical Column*). — On the calculation of inequalities of a high order. Application to the long-period lunar inequality caused by Venus, by M. Maurice Hamy. — Distribution into four groups of the first  $n$  numbers, by M. Désiré André. — On electric oscillations, by M. Pierre Janet. A gap in a circuit containing a high resistance of some 20,000 ohms is bridged by another containing a coil resistance with self induction and a bridge resistance without. The terminals in the same gap are also connected with a condenser, and a Mouton's *disjoncteur* is introduced in the circuit, rotating at a high speed. The differences of potential between the terminals of the two resistances are measured by an auxiliary condenser and a ballistic galvanometer. It is thus possible to determine the form of the oscillations. On suddenly breaking the short circuit in the gap, it was found that the ends of the resistance without self induction reached a constant difference of potential in a series of oscillations which were always of the same sign, whereas those of the other showed a series of positive and negative oscillations. — On some results furnished by the formation of soap bubbles by means of a resinous soap, by M. Izarn. Very thin and permanent bubbles are obtained by pounding together 10 gr. each of colophonium and potassium carbonate, adding 100 gr. of water and completely dissolving by boiling. For use, it must be diluted with four times its bulk of water. — Action of piperidine upon the haloid salts of mercury, by M. Raoul Varet. — On the exchanges of carbonic acid and oxygen between plants and the atmosphere, by M. Th. Schlössing, jun. — A new case of living *Xesthophage*, the *Orisma* twins, by M. Marcel Baudouin. — Notes on the feet of batrachians and saurians, by M. A. Perrin. — On asymmetric growth in polychaetous annelids, by M. de Saint Joseph. — Influence of moisture on vegetation, by M. E. Guin. Experiments with soils kept in a given state of humidity have led to the following conclusions. For each plant there exists a certain proportion of moisture most favourable to its growth. A high comparative moisture in the soil accelerates the growth, especially of the stem and leaves. The air being dry, fructification is slower with a dry than with a humid soil. Inflorescence is retarded either by dry soil or by moist air, and is hastened by the reverse con-

ditions. The most favourable conditions for exuberant growth of flowers are a moist soil and dry air, especially the latter—Researches on the mode of production of perfume in flowers, by M E Mesnard By the action of pure hydrochloric acid on sections immersed in strongly-sweetened glycerine, the essential oils are easily separated. It is found that the oil is generally located in the epidermic cells of the upper surfaces of the petals or sepals. In every case the oils appear to have been derived from chlorophyll. The perfume is not given off until the oil is sufficiently freed from the intermediate products, and it exhibits some inverse relation to the amount of tannin and pigment produced in the flower—On the existence of a condenser apparatus in the *Uredines*, by M Paul Vuillemin—On the presence of *Actinocamax* in the Pyrenean chalk, by MM Roussel and de Grossouvre—Stratigraphic consequences of the preceding communication, by M A de Grossouvre—On the formation of the Arve valley, by M Emile Haug—On an experiment which appears to produce an artificial imitation of the doubling of the canals of Mars, by M Stanislas Meunier

## THE NEW UNIVERSITY QUESTION

THE correspondence between Prof Huxley and Prof Pearson which has appeared in the *Times* is not pleasant reading. With infinite pains and trouble an Association had been formed to support the foundation in London of a university of a certain type. A nucleus of the most eminent teachers or ex-teachers in London had collected around them a powerful body of supporters from the provinces. In Prof Huxley as President, and Sir Henry Roscoe as Vice-President, the Association secured the services of two men distinguished both as professors and for their knowledge of affairs. It appears to have been less fortunate in its secretary. Prof Karl Pearson had some difference with his fellow committeemen on a question of procedure. He himself has described the divergence as not fundamental and has publicly stated that he believes that the other members of the committee were aiming at securing the establishment of a university of the type which he himself approves. So comparatively trifling was the issue, that, according to Prof Huxley, Prof Pearson himself proposed that the reason to be given for his resignation should be "pressure of work." No doubt can therefore exist as to the cogency of this motive. His position was apparently even more clearly defined by his not voting against the course of action proposed on the occasion of a meeting which was shortly to take place between the Senate of the University of London and the Committee of the Association, and by his spontaneously pledging himself "to say nothing as a member of the deputation, contrary to what was then agreed to."

It is therefore no wonder that Prof Huxley was surprised, when on the very next day Prof Pearson wrote to the *Times*, discussing resolutions which Prof Huxley regarded as confidential and accusing his colleagues of various offences, of which the day before he thought so little that he had voluntarily stated that "pressure of work" was the reason to be given for his resignation.

One good result may perhaps follow from Prof Pearson's action. Owing to the sense which has unfortunately been attached to the word "absorb," and to the assumption that the title "Professorial University" meant a University governed solely by Professors, an opinion has got about that the members of the Association are impracticable persons, who have propounded an unworkable scheme. It is true that both accusations are directly met by the published programme of the Association. It is there made clear that a voluntary absorption is all that is aimed at, and that laymen as well as experts are to have a share in the management of the University. Prof Pearson's defection has made it still more obvious that the Association scheme is intended, not to gratify theorists, but to support a policy which is capable of realization.

Prof Pearson declares that he desires a University on the model of Berlin, but the question at once arises, Is the model to be followed exactly, or are modifications to be introduced? Is the University to be free from all State control?

Prof Huxley desires that it shall be free, and under existing circumstances we cordially agree with him. Let the State, if it will, nay as it must, support and subsidize the new University as it supports the British Museum, but let the control of the one, as of the other, be in the hands of an independent Governing Body. But, if this condition is realized, there is at once a fundamental difference between the actual University of Berlin and the possible University of London. The external element furnished in Germany by State control must in England be supplied by lay members of the Governing Body, and the difference thus established will run throughout the whole of the constitution.

Prof. Huxley publishes in his letter to the *Times* an outline of a scheme for the organization of the University which is too interesting to be omitted here. He explains that he gives the rough notes on which his evidence before the Gresham University Commission was based.

The scheme is as follows —

"Do not venture to ask for all I want, but for as much as it seems possible to get on the way to that."

"Suggestions tentative and open to modification."

"(a) Retain title and prestige of University of London, reorganize it in such a manner as to secure general uniformity and efficiency of work with freedom and elasticity. In short, unify without fettering."

"(b) Make the institutions which contain technical schools of theology, law, medicine, engineering, and so on into colleges of the University. Let these examine their own candidates for degrees, under conditions determined jointly by them and the Senate of the University, and present such as they declare fit to the University for *ad eundem* graduation."

"(c) Deal in the same way with institutions giving adequate instruction in the other categories of University work—if they so please, or let the University examine."

"(d) Provide ample means for instruction in the modes of advancing natural knowledge and art, either in material connexion with the existing University or in particular colleges."

"(e) Professoriate to have large but not preponderant representation in Senate, and wide, but not exclusive, influence in regulating instruction and examination in accordance with the general aim at unification."

"(f) All state and municipal contributions, private endowments and University fees for instruction and examination to be paid into a University chest. All professorial staff and current expenses (save in cases that may be reserved) to be paid out of the University chest, also building and fitting expenses where there is no sufficient endowment of a college. The payment of the professorial staff to be primarily regulated by the kind and amount of the work done for the University, not by number of students."

"(g) No bar to be placed in the way of any one who desires to profit by any description of University instruction. If, after trial, he does not profit, time enough to exclude. Value of exclusion as disciplinary measure."

Any one who takes the trouble to compare this scheme with the original programme of the Association will see that they are in close accord. It is true that the Association put forward the complete voluntary absorption of the colleges as the result most to be desired, but it distinctly contemplated the possibility of relations between the University and institutions or colleges which were not completely absorbed, and it will be seen that the only terms on which Prof Huxley will permit relations to be established between the University and the colleges secure to the former a very large measure of authority.

Prof Huxley himself describes his scheme as of a tentative character, but whatever plan be finally adopted it is desirable that the real aims and objects of the Association shall be fully understood

It is desired that there shall be one University in London which shall be a central authority to organize and improve higher education

No reasonable person has ever supposed that the existing University of London was to be destroyed as a sort of peace-offering to its critics, or that existing colleges were to be ignored or dragooned into self-effacement. What is desired is that the Senate of the existing University should be reconstituted by the addition of professors teaching under the control of the University and by a reduction in the number of its lay members, if, with the new additions, it would otherwise be of unwieldy size

It is desired that a share in the benefits to be obtained from the University should be given to any college only in so far as it is willing to put into the hands of the University the appointment and control of those of its chairs which might be recognized by the University. It is hoped that the advantages which would accrue from this partial fusion would be so great as to lead to the gradual voluntary "absorption" of the colleges. To make this desirable end attainable it is necessary that the College Councils should not be represented, as such, on the Governing Body of the University, but no objection would, we believe, be felt to temporary arrangements which might facilitate the inauguration of the new state of things

The sooner it is clearly understood that the Association is the result of the labours and the exponent of the views of the "practical men" who are, according to Prof Huxley, to be found in the professorial ranks, the better it will be for the Association and for London. Prof Pearson's withdrawal from the secretaryship appears, under all the circumstances, to afford a sufficient guarantee of this

#### IN SAVAGE ISLES AND SETTLED LANDS

*In Savage Isles and Settled Lands. Malaysia, Australasia, and Polynesia, 1888-1891* By B F S Baden-Powell, Lieut. Scots Guards, F R G S (London Richard Bentley and Son, 1892)

THIS book contains the impressions of Lieut. Baden-Powell during a journey round the world of over three years' duration, jottings limited chiefly to his own personal doings and observations. The journey was evidently a leisurely peregrination with many divergences to places of interest off his direct route out to Brisbane in Queensland, whither he was bound to assume official duty on the staff of the governor of that colony, and an equally unburied saunter home again through the Pacific and America. The author does not propose to look at things with scientific eyes, and it is possible here and there throughout the book to detect that he has no profound acquaintance with the *ologies*. Consequently his book does not fall to be rigidly criticized in these pages. His eyes, however, if not scientific, were kept at all events very wide open, and what came under his own observation

is clearly and accurately described in a chatty and pleasant style and with a good deal of quiet humour. It is easy to see that the "tramp" enjoyed his trip, and the reader, drawn on by his cicerone's mood, accompanies him through savage isles and settled lands with equal satisfaction. Lieut. Baden-Powell started off through the European continent *via* Cologne and Vienna to Rustchuk, thence across Bulgaria, through which "a railway journey is not very interesting." Nevertheless, "little picturesque villages are seen nestling in the valleys, and distant glimpses of the Balkans gained." Beyond Shumla we get through the mountains and "pass through miles of swamp, the railway almost level with the water, and reeds growing up all around, in some places so high as to cut out all view from the carriage windows. Passing along the edges of large lakes, the train starts up thousands of wild fowl, which fly around till the air is quite darkened by them, and on we go, mile after mile, with more and more duck rising from the water," evidently a sportsman's paradise. Thence our guide conducts us to Constantinople and on to Egypt, and though he takes us by well-trodden paths and tells us little that is new or wonderful, he enlivens the way with a constant flow of time beguiling talk and anecdote. From Egypt Mr. Baden-Powell sets out for southern Australia, but he wanders as usual off his main road for some weeks into Ceylon and India to luxuriate amid their tropic scenery and ancient monuments. Of the three southern colonies of the Australias traversed on his way to Queensland he gives us a few brief notes. Of the latter colony, where he spent some years in the enjoyable and not very arduous duties of A D C to Sir Anthony Musgrave and Sir Henry Norman, he has a great deal that is interesting to tell. He visited much of the country, and saw something of its aboriginal as well as of its adopted natives, and found interest and amusement in both. At a vice-regal ball at Hughenden, a town 240 miles inland, he finds himself a fellow-guest with the butler of the hotel he was staying at, and his host's housemaid, "who was quite the belle of the ball, and who, when supper was served, turned waitress again. Such is society in a Bush town." "It was in this district," he continues, "that I first set eyes on some real wild blacks. The aboriginals of Australia are an extraordinary people. To look at they are quite unlike any other human beings I ever saw. A thick tangled mass of black hair crowns their heads, their features are of the coarsest, very large broad and flattened noses, small, sharp, bead-like eyes and heavy eyebrows. They generally have a coarse tangled bit of beard, skin very dark and limbs extraordinarily attenuated like mere bones. But they always carry themselves very erect. . . They wander about stark naked over the less settled districts, and live entirely on what they can pick up. . . If not the lowest type of humanity they would be hard to beat. They show but few signs of human instinct, and in their ways seem to be really more like beasts." Mr. Baden-Powell thus summarizes his opinions on Australia as a field for emigration (and those who know the Australasian colonies will recognize their truth): "The labouring man will find it a paradise; the professional man will find his profession overstocked, and the man with money to invest will probably be ruined. . . My personal advice to would-

be emigrants except of the lowest [<sup>2</sup> lower] class is like *Punch's*—Don't "

From Queensland it was easy and natural for our traveller to be attracted across to New Guinea, the land of so much myth and mystery. Here he fell in with the indefatigable administrator, Sir W. Macgregor, and was able to lend him a helping hand in the skirmishing incident on the capture of the natives of some villages guilty of the murder of several Europeans. He spent some days at Samarai, the head-quarters of the south-eastern district, and we feel sure that the almost unsurpassable panorama visible from its hill-set bungalow of "mountains wooded to the peak," and green isles, spread out on every side, basking in an azure sea, and picturesquely veiled in haze as they lessen away to beyond the horizon, must have rewarded him for his visit, even at the expense of a bout of fever. His account of what he saw and did in Papua occupies some eighty pages, and contains more trustworthy and interesting information than many of the narratives of men who have spent a much longer time in the country than Mr. Baden-Powell did. The next region he visited was the Malay Archipelago. He only gazed on Sumatra, "that extraordinary island which contains probably a greater variety of big game, of useful plants, and of wonderful scenery than any other country of its size", but he visited many of the most interesting places in Java, and the Straits Settlements, and made extensive journeys in Borneo, where he shot some of "the very extraordinary-looking proboscis-monkeys (*Larvatus nasalis*)". I should imagine," he remarks, "his ponderous nose would get very much in the way of his biting any one, and he certainly has no other means of defence." Our space will not permit us to follow Mr. Baden-Powell, through New Zealand and the various islands of the Pacific sojourned in by him, except to note his account of the preparation of "king's cava," of which he was a witness, in Samoa—

"This was a great event. None of the Consuls even had ever before partaken of 'king's cava.' But there was a certain amount of sham about it. First, the root was produced—genuine enough, I dare say. Six men then sat in a row outside the house, the nine-legged cava bowl before them. Each man was then given some water to wash his mouth out, and a packet of cava wrapped in a bit of leaf was given to each. I shuddered at the awful thought of what was about to happen. In true native fashion these nasty old men were undoubtedly going to chew the root, and I would have to swallow the nauseous stuff! I watched very carefully and was much relieved when I saw the packets collected again and put in the bowl. It was ready prepared [outside in a less orthodox and less disquieting fashion] and the little ceremony was only to represent formally the mode in which it ought to be done, the cava being 'taken as chewed.' Then the bowl was solemnly brought into the house and put on the floor at the end opposite the king."

This is an interesting instance of the evolution of what might have been as "meaningless a ceremonial as are many of those survivals of abandoned customs which are familiar to us in many other parts of the world.

From Samoa Lieut. Baden-Powell made his way home by the usual route *via* the Sandwich Islands and through the States.

"In Savage Isles and Settled Lands" is a book we can heartily recommend. It is elegantly got up, is illustrated by

excellent wood engravings, and has a map of the author's route. Nearly every page presents in a few words some bright vignette that will please and inform those who have never had the opportunity of visiting those lands and isles, and will set the home-come traveller a-dreaming with grateful satisfaction of delightful days that are past, and help him to live them over again more delightfully still in the present.

### PROPERTY

*Property Its Origin and Development* By Chas. Letourneau, General Secretary to the Anthropological Society of Paris, and Professor in the School of Anthropology (Walter Scott, 1892)

LESS than a generation ago the history of early civilization was summed up, if not in the three words hunting, pasture, and agriculture, at least in the formula of Sir Henry Maine "Society develops from family to tribe, and from tribe to State." Recent inquiries have discredited both of these formulas, and taken us back to the genesis of the family itself, and beyond civilization to barbarism and savagery. If we listen to Prof. Letourneau (to say nothing of Morgan and MacLennan), we may reconstruct the evolution of society in all its stages out of savagery by the "ethnographic method,"—"looking upon existing inferior races as living representatives of our primitive ancestors" (Preface, page ix). It must be remembered that in using this ethnographic method we assume that the order of progress has been substantially identical in all cases, and also that the simplest forms come first in time (p. 70, cf. 126). Both assumptions would need justification before the results of the new method could be finally accepted.

Prof. Letourneau had applied the method with great learning and ingenuity in his earlier book on the evolution of marriage. In the volume before us he applies it to property. He begins with a chapter on property amongst animals, ants and bees, as we might expect, are shown to be more highly developed in this matter than many men, and they have many of the vices of men. They provide for the future. Their property is that of a community, but one community wars on another for pillage. There are not only parasites, but idle aristocrats among them. The amazon ants, who cannot even feed themselves, but depend on their black slaves, are well known from Huber's description, and are a standing refutation of Solomon's high opinion of ants. On the whole, among animals, property is due simply to the instinct of self-preservation, and Letourneau ascribes it to the same origin in the case of men. Among the "anarchic hordes," which come first in his series (p. 23), and of which the Fuegians are a specimen, there is collective property. If union is strength it is weakness that first leads to union (cf. p. 368). But there is no personal property except in tools and weapons, "the immediate result of personal labour" (p. 39). Provision for the future is unknown. In the second stage (among the "republican tribes") the union is more highly organized; there is tribal government, with minute regulation of conduct in regard to the dealings of individuals with the necessities of life. The most remarkable example is perhaps that of the people of Paraguay

among whom (as our author shows) the Jesuit missionaries found and did not make a system of communism (pp. 42 seq.) In nearly all the instances of this class the sense of property was most strongly developed in regard to the hunting ground of the tribe, though (in the case of the Iroquois, &c.) it embraced the Long Houses of the clans of the tribe, an anticipation of Fourier's phalansteries. The differentiation of the clan from the tribe is ascribed to the growth of the taste for property itself (cf. p. 365). Letourneau would explain the present universality of human sympathy as a bequest to us from the days when all property was common (p. 57). The republican organization passed into the monarchical, where the tribe was governed by its chief (pp. 56 seq.). This political change was rather an effect than a cause of coincident industrial changes, especially the introduction of private property in slaves and women. "A comparison of the American tribes, placing them in a graduated series from the primitive system of communistic equality upward, plainly shows that, at least in this part of the world the establishment of aristocracy and hereditary monarchic power has merely crowned an economic evolution whereof the point of departure was the institution of slavery, and the consequent development of agriculture, whence arose the rupture of primitive equality, creation of exchangeable values, development of private property, contrast between rich and poor, foundation of castes, and hereditary succession" (p. 61). This passage, amongst others, betrays the tendency—fashionable in some quarters at the present time—to regard all social development as due mainly, if not wholly, to economic causes. Not that economists by profession are *grata persona* to our author. On the contrary, they are only mentioned to be rebuked, and their doctrines only to be caricatured (see pp. 91, 96, cf. 120, 124, &c.). But, as by some sections of German Socialists, so by Letourneau, we are given to understand that the politics, religion, and general character of a society are determined by the conditions of industry and the terms of property therein prevailing, while no sufficient allowance is made for the reaction of the former set of phenomena on the latter.

To sum up at this third stage in the development from savagery (the early monarchical system), the idea of personal property is extended from weapons and tools which a man has made, to the trees which he has planted, and then to the plot of ground he has cleared and sown. After that the idea of private property may be considered to be full formed and definitely launched on its modern career of development (p. 72). The great cause of private property is agriculture. Where there was only pasturage, as with the Hottentots, the private property was only in cattle, women, and children (p. 79). Agriculture brings us to extended forms of slavery, and to forms of property and modes of valuing and exchanging it that approach more and more to modern ideas.

We need not follow our author into the *minutiae* of his account of "primitive monarchies" and empires. He gives a survey of mankind from China to Peru, and from the earliest times to the period of Roman, feudal, and modern civilization. The earliest stages of the development are (rightly enough) treated more fully than the later, the later being the more generally known. The

differentiation of clan from tribe and of family from clan, the formation of village communities for the purpose of agriculture, the introduction of inheritance, and of private property in estates, are all traced out in chapters that are full of interest even when not above cavil.

Prof Letourneau has perhaps been too ready to point a moral for the benefit of his own generation. But after all he gives his readers the facts, and they may find their own moral, which may or may not be his. One of the best instances where the materials presented seem to justify a different moral than the one drawn from them is that of the *desa* or village community of Java. It is pronounced to have excellent results, particularly in increasing population (p. 121), and is contrasted with "the selfish African system" (p. 122), but by our author's own account it is a combination of private and collective property, not an example of the latter by itself (cf. pp. 114, 115).

The book is, we may presume, translated from the French, and this will account for the use of "alienist" for "lunacy doctor" (p. 370), "disengaging" for "analyzing" (p. 373), and "salaried" for "wages-earning" (p. 375). But, as a rule, the language is correct and clear English.

J. B.

#### LEAPER'S "OUTLINES OF ORGANIC CHEMISTRY"

*Outlines of Organic Chemistry* By Clement J. Leaper, F.C.S. Specially written for Schools and Classes connected with the Department of Science and Art (London: Iliffe and Son, 1892)

THIS little work is intended, as the title states, for the use of beginners. But the author has made the way of beginners hard, by leaving in his pages the largest collection of misprints and other slips which we recollect to have met with in so small a compass.

On the very first page, in the opening lines, there occurs a wrong formula for urea, and the book ends with a wrong formula for aldehyde-ammonia. We do not propose to convert this notice into a table of errata, but the following may be given as illustrating the sort of guidance which the beginner may expect. On p. 75, in the brief space of three lines, we meet with " $(\text{COOH}_2)$ ," " $\text{C}_3\text{H}_5(\text{OH}_2)$ " and " $\text{C}_8\text{H}_5(\text{OH}_2)\text{COOH}$ ," as representing respectively oxalic acid, glycerin, and—monoformin! The blunder, in each case, consists, of course, in placing a coefficient inside instead of outside the bracket, but we doubt whether, even with this correction, the last expression, with its carboxyl-group in place of the group  $\text{OCHO}$ , would be recognized, even by an experienced chemist, much less by a beginner, as representing monoformin.

Blunders, due to carelessness, are not confined to formulae. Thus we find "Pure white precipitate of silver oxide" (p. 13), whereas the context shows that silver chloride is meant, "ethene dichloride,  $\text{C}_2\text{H}_2\text{Cl}_2$ " (p. 37), "lead the gas into lime water, and note the formation of insoluble carbon dioxide" (p. 51); "by the further chlorination of methyl chloride we get ethylidene chloride" (p. 67), whilst, on p. 99, "grains" is twice given instead of "grams." But the worst blunder we have met with occurs on p. 109, where, possibly owing to a transposition of the pages of the author's manuscript, the explanations

which should follow Experiment 112 (Preparation of Ethyl Nitrite) have been moved on by a whole page, and made to follow Experiment 115 (Preparation of Nitro-ethane). The utterly bewildering effect of this jumble, which is enhanced by the unexpected re-entrance of the subject of nitro-ethane in the middle of a paragraph a little later on, cannot be realized without reading the passage.

The work is intended to combine practical with theoretical instruction. The selection of experiments is, on the whole, judicious, and the practical directions are generally good. This is not to be wondered at, as the author has evidently, in these points, followed pretty closely Prof. Emerson Reynolds's "Experimental Chemistry," even to such details as the substitution of a tin oil-can for a distilling flask (p. 99), or a peculiarity in the bending of a tube (p. 74), and to the reproduction of some of the illustrations—in every case without acknowledgment. Prof. Reynolds is not, however, responsible for the illustration on p. 17, in which the distillate from a Liebig's condenser is represented as falling from a considerable height into a flask placed below.

It is not true that (p. 12) "every organic compound containing nitrogen will, when fused with metallic sodium, convert the latter into sodium cyanide." Diazo-compounds do not yield any cyanide, and compounds containing sulphur as well as nitrogen form thiocyanate. Nor is heating a cyanide with excess of concentrated sulphuric acid (p. 76) a method of distinguishing it from a formate.

The author's style is occasionally slovenly, and sometimes worse. "Observe how the fact that oxalic acid so readily split up into  $\text{CO}$ ,  $\text{CO}_2$  and  $\text{H}_2\text{O}$  support (sic) this graphic formula for it" (p. 117).

On the whole, we suspect that teachers will prefer a text-book which calls for fewer marginal corrections.

#### OUR BOOK SHELF

*An Introduction to the Study of Botany, with a special chapter on some Australian Natural Orders.* By Arthur Dendy, D.Sc., and A. H. S. Lucas, M.A. Small 8vo, 272 pages with about 30 pages of woodcuts (Melbourne and London: Melville, Mullen and Slade, 1892).

THE authors of this little work are both teachers of Natural Science in the University of Melbourne and it is specially intended for the use of students in Australia. With this object in view it would have been better perhaps to have selected common Australian types to illustrate the life history of the great divisions of the vegetable kingdom; but *Pinus* is taken as a representative of gymnosperms and *Vicia* of angiosperms. Whether these plants are both easily procurable in Australia we are unable to say, but even in that case it would have been better to have taken native plants. Possibly the preparation of illustrations may have influenced the authors, for they are largely, in the first part, "modified," "simplified," or "adapted" figures from well known books, or they are simply copied. Taken as a whole, we do not doubt that this primer will prove useful to students, but it needs much revision to make it what it ought to be. Here and there, where we have tested it, we have found serious shortcomings. Take for example the account of the divisions of the vascular cryptogams.

"1. *Filicinae*.—These are the ferns which constitute a very large and interesting subdivision. The full account already given of the common bracken renders a detailed

description unnecessary in this place. There are two principal subdivisions of the *Filicinae*, the homosporous, which produce only one kind of spore, and the heterosporous, which produce large megaspores and small microspores. The former include all the ordinary ferns and are again subdivided into six 'families,' of which the Polypodiaceæ are the best known and most abundant, including most of the common ferns, such as *Pteris*."

One would have expected a word or two respecting the heterosporous group—the *Rhizocarpeæ*, with some mention of *Marsilea*, so memorable in the history of Australian exploration, but the authors seem to have come to grief between the older and newer classifications of vascular cryptogams, for in another place (p. 90) we read of "heterosporous ferns." The definition of the *Lquisetinae* contains no reference to the spores, and the description of the *Lycopodiinae* contains no information at all. It runs thus: "This group includes the club-mosses (*Lycopodium*) and the beautiful *Selaginella*, a plant frequently grown in conservatories for decorative purposes. They are all of rather small size, and are popularly spoken of as "mosses" owing to the general appearance of the plant with its numerous very small leaves."

Comment on such a description would be superfluous. In the classification of the cellular cryptogams, lichens are altogether left out, and are apparently not mentioned anywhere. In fact the same incompleteness and inexactness pervades the book, which opens with a eulogistic preface by W. Baldwin Spencer, Professor of Biology in the University of Melbourne. W. B. H.

*A German Science Reader* (Modern German Series) Compiled by Francis Jones, F.R.S.E. (London: Percival and Co., 1892.)

THE idea of introducing to English readers extracts from the works of many well known German scientific authorities will be thoroughly welcomed. The author has brought together sixteen very interesting articles on several branches of science, supplemented with notes, in which difficult passages are translated, and a glossary of the technical terms not usually found in dictionaries. Among the articles we may mention, Electric Telegraphs by Bernstein, Ice and Snow by Kantz, Air by Muller, Aniline Dyes by Kekulé, Spectrum Analysis by Kirchhoff and Bunsen, &c. W.

*More About Wild Nature.* By Mrs. Brightwen. (London: T. Fisher Unwin, 1892.)

MRS. BRIGHTWEN'S book on "Wild Nature Won by Kindness" was so widely appreciated that she has been encouraged to prepare a second volume of the same general character. It speaks well for her knowledge of animals, and for her interest in their habits, that the new sketches are written in as fresh and bright a style as if she had never before occupied herself with the mass of subjects with which she deals. She is a careful and accurate observer, and all readers who care for natural history will find much to please them in the facts and impressions she records. The author's illustrations add greatly to the charm of the text.

#### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended or this for any other part of NATURE. No notice is taken of anonymous communications.]

#### Arborescent Frost Patterns

ON Sunday last, December 4, I observed a curious phenomenon, which I do not remember having ever seen before in the streets of London. Along the Euston Road, the Marylebone

Road, and other thoroughfares having an east and west direction the paving flags were all covered with a striking, vegetable-like pattern which might be most appropriately described as an arborescent tracery. The pattern was not formed of the usual small and delicate frost figures such as we are familiar with on window panes, but was made up of huge and boldly fronded designs such as shown in the sketch, which I hurriedly made on the spot —

The "fronds" were from one to two feet in length, and often most gracefully curved. A keen wind was blowing at the time from a few degrees north of west and the flags had evidently been coated with a thin layer of mud from the previous night's rain. I attribute the pattern to the rapid freezing and evaporation of the water in this surface layer of mud which was going on during the morning. I only noticed the tracery along east and west thoroughfares, in sheltered streets not swept by the cold wind no design was visible. The phenomenon may be known well enough to others, but by many, like myself, it may have hitherto been passed over unnoticed. My chief object in sending this description is to call attention to the very vegetable-like appearance of the pattern. If allowed to dry in a calm atmosphere and then buried under a fine alluvial or other deposit a record would be preserved which the future geologist might at first sight be tempted to read as "vegetable remains." I have seen very similar tracery in the London clay about Clacton on Sea and elsewhere. R MELDOLA

#### Ice Crystallites

THE interesting facts recorded by your correspondent C. M. Irvine on p. 31 recall some unrecorded observations of my own. On several occasions during recent winters I have observed these crystallographic forms of ice on a gravel walk by the side of my lawn, in places where, owing to faulty gradients, the water does not completely drain away at the surface, and the ground just below the surface is in consequence more saturated with water than at other spots. The acicular ice forms have appeared in bundles standing up between the pebbles and capped by earthy material, just as described by Mr. Irvine, and in previous communications to NATURE by Mr. B. Woodd Smith (see his letter on p. 79). The nature of the soil agrees with that described by these two observers, so far as permeability to water is concerned, and I think they appeared on the occurrence of clear frosty weather after a thaw and melting of previous snow. My observations, however, extended further than theirs appear to have done. I was at the time pursuing the study of the glassy acicular crystallites of sulphur (which are erroneously described as "crystals" in most textbooks on chemistry). These, on examination with polarized light (as I have described elsewhere) are found to be destitute of any crystalline internal structure (in fact truly vitreous or isotropic masses in spite of their crystallographic outlines), such structure developing, as devitrification proceeds, by crystallization in the orthorhombic system, to which the outlines of the crystallites do not conform.

In NATURE (vol. xxxvii. p. 104) is a letter from myself, recording some observations on the vitreosity of ice, as exhibited under certain suitable conditions by hailstones, and referring to a previous letter (*Ibid.* vol. xxxvi. p. 77), wherein the vitrification and devitrification of water was suggested as the possible

cause of certain structural phenomena observed in them from time to time. It was with those ideas present to my mind that during recent winters I have made an examination of the acicular ice forms referred to, which struck me as made up of unusually clear and transparent ice. On taking my microscope out of doors, fitted with a polarizing apparatus, when the temperature was a few degrees below freezing, with a thick overcoat on to prevent the heat of one's body from affecting the ice-needles, I found that, on taking them from the ground and placing them at once on the stage between crossed "Nicols," they appeared to be *completely isotropic*, as they had no reaction on polarized light. I have concluded, therefore, that these ice needles are strictly analogous (physically) to the prismatic crystallites of sulphur, and they resemble precisely the microscopic lathe shaped forms, into which I have seen a perfectly clear minute plate of sulphur-glass break up in the first stage of devitrification. The explanation suggested by Mr. Woodd Smith, that they may have been formed by a slow growth of ice at their base, the molecular movement of water in the soil keeping up the supply so long as refrigeration continued, has seemed to me the most natural one; their isotropic molecular structure is no doubt due to the rapidity of freezing owing to a sudden fall of temperature at the spot. A. IRVING

Wellington College, Berks, November 27

#### The *Volucella* as Alleged Examples of Variation "almost Unique among Animals"

IT is barren work for the parties in a controversy merely to deny each other's statements without adducing further evidence. Mr. Bateson first stated that var. *mystacea* did not mimic *Bombus muscorum*. I replied that it did, and the statement in my letter in no way depended on the case at the Royal College of Surgeons, but on a careful comparison of the insects in the Oxford Museum. It is useless for me to repeat that I regard it as an example of mimicry, not indeed equal to that afforded by the same fly and *Bombus hortorum*, but far better than many others which are generally believed to be instances of this principle (such as the resemblance of *Clytus arctus*, or even the resemblance—admitted by Mr. Bateson in his first letter—of *Volucella mans*, to a wasp). I therefore propose to furnish the Editor of NATURE with photographs of the *Volucella* and humble bees for reproduction, so that readers can judge of the matter for themselves. I will do my best to obtain a negative which shows the coloured bands.

Although I believed that the two London Museums supported my view, it will be obvious to any one who reads the letter that I did not rely on such support, but on my own comparison of the insects.

Mr. Bateson has offered no further evidence in support of his remarkable assertion that the variation of the *Volucella* is unique. I am not surprised that he should pass over this part of my letter, for I felt sure that there was no further evidence to offer. It will be remembered that this evidence was contained in the "brief statement of facts" given in his first letter, and is practically summed up in the sentence "This fly exhibits the rare condition of existing in two distinct forms in both sexes." In assuming this rarity to be so excessive that the words "almost unique" may be applied to it, and in evidently considering that we must proceed as far as the peach and nectarine in order to find a parallel, Mr. Bateson exhibits a want of acquaintance with the facts of variation which is very surprising in one who is believed to have spent some years in their study. For there is no essential biological difference between this variation and many others, examples of which I gave in my last letter, and which could easily be multiplied. In fact, many a "showcase" would have corrected such a mistake. Compared with the magnitude of this erroneous statement in Mr. Bateson's first letter, the details under discussion assume very small proportions. In considering that "no speculation is needed to enhance the exceptionally interesting facts of the variation and the resemblances of the *Volucella*," it would appear that Mr. Bateson seeks to replace that most invaluable servant of science, speculation, by far reaching and unsupported assertion.

In his last letter Mr. Bateson says "it is admitted that in making this statement Mr. Poulton relied not on original authorities, but on the general impression of others." So far from this being the case I stated my belief that the impression is prevalent among those who are original authorities on the Hymenoptera and their parasites, and I also showed that nothing

is advanced by the authorities quoted by Mr Bateson which can be regarded as antagonistic to this impression by any one who knows a little about the working of heredity in insect varieties.

A word about "showcases." I hope that no reader of NATURE may be led to think lightly of these as a means of instruction, and as one of the chief objects of a great museum because Mr Bateson states that there is a wrong identification in one at the Royal College of Surgeons, and because of the distinction which he is so careful to draw between these and other cases. Some of the most valuable specimens in the world are in "showcases." They form one of the most admirable features in modern museum arrangement, and the best material obtainable is set aside for them. This is equally true on the continent and in our own country, where Prof Sir W. Flower and Prof Stewart have devoted an immense amount of time and labour to this department, an important recent feature of both their museums being the illustration of the uses of colouring in animals. Prof Lankester too is developing the same method of instruction with great success in the Oxford Museum.

It is in no way remarkable or reprehensible that four recent writers (Mr Lloyd Morgan, Mr Beddard, Mr Romanes, and myself) concerned with this subject and knowing the care taken in choosing these illustrations, should also make use of some of them in their published works.

One "difficulty" brought forward by Mr Bateson is so futile that I did not allude to it before, and only refer to it now because he repeats it. He seems to think that doubt is thrown on the theory of mimicry because *V. pellucens* does not resemble a wasp, and yet lives in its nests—as if any believer in natural selection maintained that all closely allied forms must defend themselves in the same way.

As to Mr Bateson's statement at the end of his letter that he only intended to draw attention to the matter (and not to hurt me thereby), I can only say that this statement implies an extraordinary want of acquaintance with the niceties of the English language. It is so easy to correct mistakes without leaving anything but a feeling of gratitude in the mind of one who has made them, that, in justice to Mr Bateson's intelligence, I am compelled to doubt the accuracy of his memory. Oxford, November 27. EDWARD B. POULTON

#### "A Criticism on Darwin"

I WRITE to protest against what appears to be a growing habit on the part of certain publishing firms of advertising their books in a most misleading manner, viz by selecting any phrase from a notice of the book which may serve to indicate that the writer's opinion on the work as a whole is favourable, whereas, if quoted with its immediate context, the passage would prove the precise opposite. For example, I see in NATURE and elsewhere an advertisement of Mr David Syme's book "On the Modification of Organisms, a Criticism of Darwin" (Simpkin, Marshall, and Co.), in which I am quoted as having called the writer "a shrewd critic." Standing by itself these words imply that I have somewhere recommended the work as well worthy of perusal. The fact of the matter, however, is, that the words occur in a foot note which I added to the proof of my recently published book on "Darwin and After Darwin," for the expressed purpose "of showing the extraordinary confusion of mind which still prevails on the part of Darwin's critics, even with reference to the very fundamental parts of his theory." Elsewhere in the same foot-note I refer to the writer's "almost ludicrous misunderstanding," and conclude by saying that he "shows himself a shrewd critic in some other parts of his essay, where he is not engaged especially on the theory of natural selection." I may now add that the only parts of his essay to which these advertised words apply are those where he treats of the deleterious effects of in-breeding.

GEORGE J. ROMANES

#### Animals' Rights

I AM not surprised that you should find my essay on "Animals' Rights" an "absolutely useless" one, for I certainly did not design it to be a congenial hand book for the apologists of vivisection. Nor do I the least object to your drawing what conclusions you like from the premises laid down by me, even though you seek your justification of vivisection from the very definition that seems to me to be most clearly condemnatory of it. But, as a matter of fact,

and not of personal opinion, I beg to point out that you have utterly misrepresented the leading principle of the book, and that the two contradictory definitions of animals' rights, which you attribute to my confusion of mind, are in reality the phantom creation of your own. On p. 9, in referring to Herbert Spencer's definition of human rights, I claim for animals a "due measure" (not an equal amount) of the same "restricted freedom"—a claim which by no means prohibits all use and employment of animals, as you conveniently assume. On p. 28 I give, not a second definition, but a repetition and amplification of the one given on p. 9, and the "due measure of restricted freedom" is explained as being "a life which permits of the individual development, subject to the limitations imposed by the permanent needs and interests of the community." Surely this is intelligible enough, yet the reviewer has utterly failed to understand it. H. S. SALT  
38 Gloucester Road, N.W., November 26

#### Induction and Deduction

MISS JONES has not quite understood me. I maintain that definitions should be arbitrary, but not necessarily that they should be made at random. If they are so made it will, as she points out, seldom happen that they turn out useful, or have any real applications, though this would not affect their logical validity if it amused any one to make them and investigate their consequences. Such definitions with no real applications are actually made by pure mathematicians. The peculiar value of the definitions of geometry consists however in the fact that they have so many real applications, and it is only by a long process of survival of the fittest that a few such happy definitions are weeded out from among the many which lead to nought. The definitions of geometry could not now be laid down at random, but they are none the less arbitrary, for they require no support from any *a priori* considerations. EDWARD T. DIXON  
Trinity College, Cambridge, November 28

#### The Present Comets

I HAVE to notice the following mistake in my letter<sup>2</sup> which appeared in NATURE (vol. xli. p. 561). I called comet Brooks, comet "c." I now find it should be called comet "d."

I have since writing been quite satisfied that the head of comet Swift extends less towards the  $\alpha$  than towards the  $\delta$  (as suggested in my letter). T. W. BACKHOUSE

West Hendon House, Sunderland, November 26

#### The Afterglow

AFTER witnessing, with Profs Lyon and Orr, remarkable effects of afterglow on November 27, I waited for the next issue of NATURE (No. 1205), in the expectation that similar phenomena would be mentioned as having been seen in the British Isles. Curiously enough, the letter on "Afterglow" in that issue comes from Honolulu, dated November 8. It is possible, however, that the effects of volcanic dust from one of the great eruptions of the past summer are now beginning to be noticeable in opposite hemispheres. The Krakatau eruption of August 27, 1883, appears to have caused exceptional afterglows in Honolulu on September 5, and in Western Europe by November 9, in the same year.

From the top of Killiney Hill, on November 27, at 4.30 p.m., we witnessed an extraordinary combination of cloud effects, such as I do not remember having seen since the winter of 1883-4. On the west, dense clouds were forming upon Two Rock Mountain, and streaming down into the hollow of Carrickmines, but beyond them a clear golden sunset, passing above into green and intense blue, was visible above the summits of the hills. Fleecy cirrus clouds in the zenith were a delicate pink against clear blue, and this glow extended to all the higher cloud-masses in the east, until the sea itself became rose pink by reflection. But in the extreme east the exceptional magenta tints, almost violet, that characterized many of the Krakatau glows, were strikingly apparent, though in part veiled by the low grey cloud of the Channel. These effects were at their maximum when the sun had set half an hour, they would doubtless have been of much longer duration but for the near clouds forming on the mountains.

One's thoughts at once turned to the great eruption of Sangay in the Philippines, which occurred, however, as far back as

June 7 of this year. Weather and locality have been against my seeing clear sunsets until to-day, when no unusual effects were noticeable, but Mr Bishop's letter makes it possible that in other places similar effects may be observable.

GRENVILLE A J COLE  
Royal College of Science for Ireland, Dublin, December 4

### ELECTRICAL STANDARDS

THE following supplementary report has been presented to the President of the Board of Trade by the Electrical Standards Committee —

To the Right Hon A J Mundella, M P, President of the Board of Trade

Subsequently to the presentation of our former report to Sir Michael Hicks-Beach in July, 1891, we were informed that it was probable that the German Government would shortly take steps to establish legal standards for use in connection with electrical supply, and that, with a view to secure complete agreement between the proposed standards in Germany and England, the Director of the Physico-Technical Imperial Institute at Berlin, Prof von Helmholtz, with certain of his assistants, proposed to visit England for the purpose of making exact comparisons between the units in use in the two countries, and of attending the meeting of the British Association which was to take place in August in Edinburgh.

Having regard to the importance of this communication, it appeared desirable that the Board of Trade should postpone the action recommended in our previous report until after Prof Helmholtz's visit.

That visit took place early in August, and there was a very full discussion of the whole subject at the meeting of the British Association in Edinburgh, at which several of our number were present. The meeting was also attended by Dr Guillaume, of the Bureau International des Poids et Mesures, and Prof Carhart, of the University of Michigan, U S A, who were well qualified by their scientific attainments to represent the opinion of their respective countries.

It appeared from the discussion that a few comparatively slight modifications of the resolutions included in our previous report would tend to secure international agreement.

An extract from the report of the Electrical Standards Committee of the British Association, embodying the results of this discussion, was communicated to us by the Secretary, and will be found in the appendix to this report.

Having carefully reconsidered the whole question in view of this communication, and having received the report of the sub-committee mentioned in resolution 14 of our previous report, we now desire, for the resolutions contained in that report, to substitute the following —

#### RESOLUTIONS

(1) That it is desirable that new denominations of standards for the measurement of electricity should be made and approved by Her Majesty in Council as Board of Trade standards.

(2) That the magnitudes of these standards should be determined on the electro-magnetic system of measurement with reference to the centimetre as unit of length, the gramme as unit of mass, and the second as unit of time, and that by the terms centimetre and gramme are meant the standards of those denominations deposited with the Board of Trade.

(3) That the standard of electrical resistance should be denominated the ohm, and should have the value 1,000,000,000 in terms of the centimetre and second.

(4) That the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice 14.4521 grammes in mass of a constant cross sectional area, and of a length of 106.3 centimetres may be adopted as one ohm.

(5) That a material standard, constructed in solid metal, should be adopted as the standard ohm, and should from time to time be verified by comparison with a column of mercury of known dimensions.

(6) That for the purpose of replacing the standard, if lost, destroyed, or damaged, and for ordinary use, a limited number of copies should be constructed which should be periodically compared with the standard ohm.

(7) That resistances constructed in solid metal should be adopted as Board of Trade standards for multiples and submultiples of the ohm.

(8) That the value of the standard of resistance constructed by a Committee of the British Association for the Advancement of Science in the years 1863 and 1864, and known as the British Association unit, may be taken as 9866 of the ohm.

(9) That the standard of electrical current should be denominated the ampere, and should have the value one-tenth (0.1) in terms of the centimetre, gramme, and second.

(10) That an unvarying current which, when passed through a solution of nitrate of silver in water, in accordance with the specification attached to this report, deposits silver at the rate of 0.001118 of a gramme per second may be taken as a current of one ampere.

(11) That an alternating current of one ampere shall mean a current such that the square root of the time-average of the square of its strength at each instant in amperes is unity.

(12) That instruments constructed on the principle of the balance, in which, by the proper disposition of the conductors, forces of attraction and repulsion are produced, which depend upon the amount of current passing, and are balanced by known weights, should be adopted as the Board of Trade standards for the measurement of current whether unvarying or alternating.

(13) That the standard of electrical pressure should be denominated the volt, being the pressure which, if steadily applied to a conductor whose resistance is one ohm, will produce a current of one ampere.

(14) That the electrical pressure at a temperature of 15° centigrade between the poles or electrodes of the voltaic cell known as Clark's cell, prepared in accordance with the specification attached to this report, may be taken as not differing from a pressure of 1.434 volts, by more than one part in 1000.

(15) That an alternating pressure of one volt shall mean a pressure such that the square root of the time-average of the square of its value at each instant in volts is unity.

(16) That instruments constructed on the principle of Lord Kelvin's quadrant electrometer used idiosatically, and, for high-pressures, instrument on the principle of the balance, electrostatic forces being balanced against a known weight, should be adopted as Board of Trade standards for the measurement of pressure, whether unvarying or alternating.

### ON THE PHYSIOLOGY OF GRAFTING<sup>1</sup>

THE volume before us contains the record of several years of research upon the effects of different forms of grafts (using the term in its widest significance) in the vegetable kingdom.

<sup>1</sup> "Ueber Transplantation am Pflanzenkörper. Untersuchungen zur Physiologie und Pathologie." Von Dr. Hermann Vöchting. Mit 11 lithographierten Tafeln und 14 Figuren im Texte. (Tübingen: Laupp, 1892.)

Opening with an historical introduction which deals briefly with the development of the art from classical times down to the present day, the author proceeds to indicate the general scope of his own investigations, and to describe the methods of experiment which he employed. The immediate problems which he sets himself to solve are contained in two questions which occur on an early page of his book, namely—Is it possible to remove parts of a given plant and transplant them to any other position in the same or a similar plant? And upon this question follows the second—What is the nature of the reaction which occurs between the newly-introduced portion and the surrounding tissues?

But although these form the proximate questions which are to be answered by means of a large number of well-conducted experiments, it soon becomes clear to the reader that the chief interest which attaches to the results obtained depends on their application to the theory of polarity of cells and tissues which Prof. Vöchting has already put forward elsewhere.

The plants chiefly (but by no means exclusively) used in the investigations were *Beta vulgaris* and *Cydonia japonica*. The former is of a fleshy and succulent character, whilst the latter is a woody plant which happens to be specially adapted to the various operations of grafting, and, as it is a perennial, it admits of the results of the experiments being watched for a considerable period of time. Prof. Vöchting distinguishes in every part of the plant between a "shoot-pole" and a "root-pole," and these he considers to be always present, however small the plant member, or piece of excised tissue, may be. The polarity manifests itself at the free surfaces, much as the effects of the magnetism of a bar magnet are visible at its ends, and moreover, just as the pieces of a broken magnet are themselves duly polarized, so also fragments of tissue exhibit relations of polarity identical with those characteristic of the organism from which they were derived.

The first precaution necessary to secure success in grafting is to respect the existences of the shoot- and root-poles, and to insert the scion in such a way as to bring its poles into due correspondence with those of the stock. Acting upon this principle it is found that, generally speaking, any member may be grafted on any other member unless there is some special reason to the contrary, such as may be connected, for example, with nutrition or water-supply. The leaf of the beet will "take" if grafted on a root, and *vice versa*, and it was also found that it was possible, in the case of roots with diarch bundles, to effect a union even when the xylem planes in the two portions were made to cross each other at right angles, analogous results were also obtained with leaves. Hence the author concludes that there is no inherent fixity in the organization of plants which predetermines a definite sequence of the chief members of which they are composed.

Experiments were made with the object of determining the mutual reactions between the stock and the scion, and the conclusion arrived at is that beyond such changes as may be referred to nutritional and similar causes, the two remain unaltered, at least in so far as their specific characters are concerned. Prof. Vöchting criticises unfavourably the various alleged cases of the so-called "graft-hybrids," and points out that even in one of the best authenticated examples, that of *Cytisus Adami*, all attempts to produce the hybrid afresh have resulted in failure.

The most interesting part of the book is occupied with the account of researches into the behaviour of transplanted portions of tissue, the direction of whose "polarity" does not coincide with that of the parts into which they are introduced. When the inserted portion of tissue is rotated on its longitudinal axis so that its own tangential surfaces are applied to the radial ones of its new host,

difficulties arise in the accomplishment of a complete union, and these difficulties are further increased to a maximum when the tissue is put in upside-down, so to speak, that is with its own poles presented to *similar* poles in the stock. A great number of experiments were instituted to investigate these reactions, but space forbids any attempt to do more than briefly summarize the most important points. In the case of *Cydonia japonica* a ring of rind was cut out of a twig and replaced in the reversed direction. In many cases the twigs behaved as if the tissue had not been restored at all, simply dying, whilst in others a subsequent healing took place. This healing was accompanied by a swelling at the upper junction, together with the appearance of a ridge of tissue which was formed along the longitudinal suture of the ring from above downwards and was derived from the cambium of the ring, and not by an ingrowth of callus from the uninjured cortex of the twig, as might perhaps be supposed. In this way connection between the interrupted rind was re-established, and growth recommenced. But both at the edges of the tissue-ridge, and also between it and the original underlying xylem, the cell elements were found to be disposed in a remarkable manner, forming curved unions with the cells of the healthy tissues. For the histological details the reader is referred to the original treatise, suffice it to say that Prof. Vöchting believes that he has found in the appearances thus presented, additional evidence for the validity of his theory of the polarized condition of living tissues. He conceives of these polarities as properties which are the expression of the innermost relationships existing between the constituents of which cells are built up. He further regards the polarity of any tissue as irreversible when once the direction has been imparted to it, and he finds justification for this view not only in the details of his own experiments on grafting, but also in the results of investigations conducted by Kny and others, on the effects of compelling parts of plants to grow in a reversed position. After discussing some of the objections to his theory, without, however, disposing of them all, the author concludes by stating, with considerable reserve, some of the wider applications of his theory in explaining geotropism and other allied phenomena.

The book certainly forms one of the most important of the recent contributions to plant physiology, and the experimental details are well illustrated in the eleven plates which accompany the text, whilst the diagrams in the body of the work serve to render the author's theoretical views more intelligible.

J. B. F.

## NOTES

A GOLD MEDAL is to be presented to M. Pasteur on December 27, his seventieth birthday.

ON Monday Lord Durham laid the foundation stone of a new wing of the College of Science, Newcastle, which, like the College of Medicine in the same city, is a branch of the Durham University. The College of Science was established at Westgate Hill, Newcastle, in 1871. Lord Armstrong laid the foundation stone of the present premises at Barras Bridge in 1887, and in the following year the existing wing was opened by the Marquis and Marchioness of Lorne. The success of the institution is strikingly indicated by the fact that the increase in the number of students has rendered a new wing absolutely necessary.

DR. WERNER SIEMENS, the well-known electrical engineer, died at Berlin on Tuesday. He was seventy-six years of age.

MR. W. H. PREECE, F.R.S., has been appointed a member of the Royal Commission on Electrical Communication with Lighthouses, &c., in the place of Mr. Edward Graves, deceased.

MR W MATHIEU WILLIAMS, who had a considerable reputation as a metallurgist and a popular writer on scientific subjects, died at his residence, near Willesden, on November 8. He was in his seventy-fourth year. Among his writings are his well-known books on "The Fuel of the Sun," "Science in Short Chapters," and "Through Norway with a Knapsack."

We have to record the death of two distinguished Continental cryptogamists, Dr F v Thumen, the well known mycologist, formerly Director of the Chemico-Physiological Experiment Station at Klosterneuberg, and Dr C M Gottsche, of Altona, one of the authors of the *Synopsis Hepaticarum*, and one of the leading authorities on Mosses and Hepaticæ, in the eighty-fourth year of his age.

The Master and Fellows of Gonville and Caius College, Cambridge, have elected as Honorary Fellows the following graduates of the college—Alexander Henry Green, F R S, bracketed sixth Wrangler, 1855, formerly a Fellow of the College, late Professor of Mathematics, Yorkshire College of Science, now Professor of Geology, Oxford; Arthur Ransome, M D, F R S, First class Natural Sciences Tripos, 1856, Physician to the Manchester Hospital for Consumption and Diseases of the Throat, and George John Romanes, F R S, Sir Robert Rede's lecturer, 1883, late Professor of Physiology in the Royal Institution of Great Britain.

An important conference on technical education was held at Newcastle on Saturday. It was summoned by the Technical Education Committee of the Northumberland County Council. Sir M White Ridley, the Chairman of the Council, said that the scheme of the Technical Education Committee, generally speaking, had opened out two progressive educational roads from the elementary day school onward—first, for day scholars, by means of scholarships, and secondly, for evening students by a graduated system of classes. The work in progress under that scheme had already been very extensive. As regarded agriculture, there had been courses of lectures on manuring land, poultry-keeping, farm stock, dairy work, &c. Educational courses had been given in mining, mechanics, electricity, engineering, ship building, &c. As regarded the fishermen also, a very successful method had been adopted of teaching the men a few plain scientific facts with regard to coastal navigation, the habits of fishes, and so on. After the delivery of the Chairman's speech the Committee's scheme was carefully discussed.

PRIZES and certificates in connection with the City and Guilds of London Institute will be presented on Monday, December 12, at Merchant Taylors' Hall, Threadneedle street, by Mr William Anderson, F.R.S. The Lord Mayor will preside.

At the General Monthly Meeting of the Royal Institution on Monday, the special thanks of the members were returned to Mr Ludwig Mond for a donation to the fund for carrying on investigations on liquid oxygen.

MR STREETER held a reception on Saturday at 18 New Bond Street for the first display of sapphires from the Montana mines. At the same time an assortment of chrysoprase jewels was exhibited, and also a black diamond, said to be the largest yet discovered. Mr Streeter also showed, among other things, a collection of different specimens of pearl-bearing oyster shell, and some curious formations of pearls in shell and loose, and in a variety of natural colours.

In the current number of the *Geological Magazine* it is noted that Mr Joseph E Carne, Curator of the Mining and Geological Museum, Sydney, New South Wales, who so ably assisted the late Mr. C S Wilkinson during the Mining and Metallurgical Exhibition at the Crystal Palace, Sydenham, in 1890, has been appointed by the Minister of Mines to the post of Geological

Surveyor. Mr Carne entered the service of the New South Wales Government in 1879.

THE French Association for the Advancement of Science has received from an anonymous donor the sum of 600 francs, to be given in two prizes (of 400 and 200 francs), to the authors of the best memoirs containing an investigation, according to local documents, of the frequency of rabies, and the prophylactic measures in operation in a department of France, *la Seine excepted*, or in a region (two or three departments) of France or of Algeria. The statistical figures must relate to ten years at least, and comprise the results of 1892. Manuscripts to be sent to the secretary in Paris before March 31, 1893. The following points are noted for investigation—The number of rabid animals, of dogs, of persons bitten, and dead through rabies, also of those vaccinated at the Pasteur Institute; separate the cases of rabies in large towns from those in the rest of the department; measures of sanitary police, their effect and difficulty of application; causes of more or less frequency of rabies, and of vaccination; measures taken in frontier departments, &c.

DR B PASQUALE has undertaken a study of the phenomena and causes of the very destructive disease of the vine known as "mal nero," his observations having been made chiefly in Sicily. The disease makes its appearance in the form of black spots and streaks on the leaves. Dr Pasquale finds it to be always accompanied by a Schizomycete, which he believes also to be its cause, and which is parasitic, especially on the tissues rich in protoplasm and in other plastic substances, such as the cambium, the medullary rays, the cortical parenchyma, and the soft bast of the axile organs.

THE *Botanical Gazette* states that, in a report to the Cornell University, Prof L H Bailey firmly establishes the commercial value of the electric light for certain winter crops, especially for lettuce. Certain kinds of plants, which are injured by the direct rays of the light, are not injured, but may even be benefited, when the light passes through a clear glass globe or through a glass roof. Auxanometric records appear to show that the light accelerates growth, but does not change its normal periodicity. This is in harmony with the observations of Prof G Bonnier, recorded in the *Comptes rendus*, who finds that the electric light promotes the formation of chlorophyll in all kinds of plants, both woody and herbaceous.

THE third appendix, 1892, of the *Kew Bulletin* has been issued. It consists of a list of the staffs of the Royal Gardens, Kew, and of botanical departments and establishments at home and in India and the colonies, in correspondence with Kew.

M EDOUARD BRANLY, Professor of Physics at the Ecole Libre des hautes études, Paris, writes to us to complain that experiments made by him are attributed to Mr Dawson Turner in our account of "Physics at the British Association" (*NATURE*, August 18, p 384). We learn that in Mr Turner's paper, and in the condensed report furnished by him for publication, full justice was done to Prof Branly's work. The reference to Prof. Branly was unintentionally omitted when the report was being cut down for *NATURE*.

MESSRS MACMILLAN & CO will publish immediately a new book by Professor Oliver Lodge, entitled "The Pioneers of Science." In this volume, which will be fully illustrated with portraits and diagrams, the author describes in popular language the history and progress of Astronomy. His aim has been to state scientific facts and laws as simply as possible, to present in turn a living figure of each Pioneer, and to trace his influence on the progress of thought.

DURING the past week barometric depressions have reached our western coasts with considerable frequency. As these dia-

turbances were passing away from our islands, sharp frosts occurred in the north, where the shade temperature fell as low as 13° in the north of Scotland on Thursday, December 1. The gales which accompanied the depressions were confined more particularly to the north and west. On Saturday, the 3rd instant, a large cyclonic disturbance appeared from off the Atlantic, and in the rear of this cold north westerly winds set in with snow or hail showers generally, in many parts of the country the snow was sufficiently heavy to interfere seriously with traffic. The temperature continued to decrease, the highest daily maxima being generally below the average for the time of year, and at places in the north and north east of our islands the maximum thermometer at times did not rise above the freezing point. For the week ended the 3rd instant the official reports show that the rainfall was greatly in excess in Scotland, and rather so in the south of England and some of the western districts, but in the eastern parts of Great Britain, and in the north of Ireland, there was a deficiency. In the south-west of England the deficiency, from the beginning of the year, is still very great, being 22 per cent of the average amount.

MR H. C. RUSSELL, in his presidential address to the Royal Society of New South Wales, mentions a very curious drift of a "current bottle" thrown from the Austrian man-of-war *Saida*, about half-way between Sydney and New Zealand. This bottle found its way through twelve degrees of latitude and four of longitude to the coast of Australia, two miles north of Tweed River, where it was found just eleven months after it was thrown into the sea. Mr Russell states that from what is known of the currents, which set strongly to the south along the coast of Australia, it seems impossible that it could have travelled direct, and that it was therefore probably carried eastward to the coast of New Zealand, and thence northward towards New Caledonia, until it got into the current setting from there to the coast of Australia, a journey of at least 2,500 miles in 335 days, and doubtless subject to many deviations which made its course longer and all the more surprising.

M. W. PRINZ, secretary of the Belgian Microscopical Society, has published an interesting paper on filiform inclusions in the quartz of St. Denis, Mons, which strangely simulate organic structures. He has at the same time discussed the origin of moss agates, and has repeated the experiments with colloid silica and certain salts by which very similar appearances are produced. The paper, which is illustrated with a plate, is a valuable contribution to the literature of a very interesting subject.

MR W. HOLLAND contributes to the December number of the *Entomologists' Monthly Magazine* some good practical hints on sugaring. Moths, he says, often come more readily when sugar is applied to the twigs and branches of the trees they feed upon, or twigs of something near their food-plant, than they will to sugar placed on the trunks of trees, *Xanthia citrago*, for instance, will hardly come at all to sugar put on the trunk of the lime tree, an occasional one only will be got in this way, but by sugaring below the tips of the outermost branches all round the tree Mr Holland generally finds about fifty on one tree, besides other species. In the case of *Xanthia aurago* again, the best place to sugar is along the outside of the beech wood beneath the ends of the overhanging branches, or on the twigs of the hedge below them. Mr Holland has repeatedly taken about 100 in a night in this way, when trunks sugared inside and outside the wood have not yielded one specimen. Other things may be got in the same way by selecting the place according to the species wanted. Among other points to which he calls attention is the necessity of recognising early what is going to be a species of the year, for every year brings some

particular kind more plentifully than usual. The sugar Mr Holland uses is "Egyptian raw," a date sugar. This is very dark and strong stuff, sand like, and free from lumps, and it mixes easily without boiling. He simply mixes it with beer, and then adds a drop or two of essence of pears just before starting out. There is rum enough in good sugar, and to add more is only to make the moths drop off before they can be bagged. "Jamaica foots" is a good sugar too, but it is lumpy and needs boiling. Old black treacle will do fairly well as a bait, but "golden syrup" Mr Holland believes to be a fraud. Beet-root sugars, or refined sugars, are of course bad, and if he happens to be in a place where he can get only these, then, and then only, he adds rum.

THE second volume of the Transactions of the Leeds Naturalists' Club, to which we referred last week, includes an interesting paper on the structure and life history of a fungus, by Mr Harold Wager, assistant lecturer and demonstrator in biology, in the Yorkshire College, Victoria University. The paper deals with a small microscopic fungus, *Peronospora parasitica*, as a type of the fungi. Mr Wager points out that, although in some respects this may not be the best type for the purpose, it has the advantage of having a comparatively simple structure and method of development easy to understand, and serving as an excellent introduction to the morphological study of the fungi. This type is also the more interesting because many structural details, which are fully described by Mr Wager, have been more fully worked out in it than in any other. The paper is carefully illustrated, and the author gives a useful summary of the methods employed in the examination of the various structures he mentions.

A NOVEL utilization of aluminium is that for the construction of aluminium slate pencils. Major von Sillich, of Meiningen, found that aluminium gives a stroke on a slate, and a German company has undertaken the manufacture of pencils based on that fact. They are 5mm thick and 14mm long. They need no pointing, and are well nigh inexhaustible and unbreakable. The writing, which is as clear as with ordinary pencils, requires a little more pressure. It can be erased with a wet sponge.

A COLORIMETER for comparing the intensity of colour in a solution with a standard solution has been constructed by Pappasoglou. It consists of two graduated cylindrical vessels of equal diameter, through which light is transmitted from below. A vertical telescope fixed above the tubes shows the two halves of the field equally illuminated if the amounts of coloration are the same. If they are not, the heights of the liquids in the tubes can by a simple contrivance be so regulated that the colours have equal shades. Under these conditions, the concentration of colouring matter is inversely proportional to the length of the column of liquid tested.

THE Trinidad Field Naturalists' Club has held its first annual meeting, and has evidently good reason to congratulate itself on its success, which has surpassed the highest expectations of the members. Mr Caracciolo, the chairman, in his presidential address, reminded the club that the gardens, plains, mountains, and rivers of Trinidad swarm with animal forms, about a good many of which very little is yet known.

THE latest instalment of the Transactions of the Institution of Engineers and Shipbuilders in Scotland includes the address by Mr Robert Dundas, president, at the opening of the present session. Speaking of railways, Mr Dundas said that a continual improvement in rolling stock generally can be noted. Larger and more commodious carriages are gradually taking the place of the smaller ones, and there is a marked increase in the application of the bogie principle, which does well, and makes an easy running carriage when properly constructed.

"Long carriages," said Mr Dundas, "cannot be built to go round ordinary curves without either a bogie or radial axle; and between the two experience leaves very little doubt as to which is the better. The radial axle is an awkward arrangement, and does not act with the same smoothness as a well constructed bogie with properly balanced springs to regulate its motion, and a bogie of short wheel base is not so good as a long one, the wheel base should always be more than the gauge to produce good results. There is no better test to determine what is good or bad in rolling stock than the effect on the permanent way."

A VALUABLE paper on the copper resources of the United States, read by Mr James Douglas before the Society of Arts on November 30, is printed in the current number of the Society's journal. Mr Douglas notes that though for many years no new copper mine has been opened, the larger and richer ones, which have been able to maintain existence in the face of depressed prices, are directing their efforts, not so much towards increasing their capacity for production as towards reducing the cost of reduction, saving, as far as possible, the precious metals associated with their ores, and securing for themselves the profits which have heretofore been made by the refining companies, to whom they sold their furnace material. "The effect of this change of policy," said Mr Douglas, "may tell upon the market. It certainly will affect the copper refineries of this country and the continent. It would seem, therefore, that the era of rapid expansion is drawing to its close, and a healthier one of economical treatment is being inaugurated. The demand for copper is so great, that, if this policy be pursued by the large existing mines, there will be room for the appearance of new competitors, without imminent risk of over-production."

MR W J L ABBOTT contributes to the new instalment of the Proceedings of the Geologists' Association an interesting note on the occurrence of walrus in the Thames valley. *Trichechus rosmarus*, Linn, has been recorded from several places on the east coast, from the Dogger Bank, and from the peat near Ely. In the Thames valley it was discovered at a depth of 33 feet 2 inches during the excavations for the new London Docks. It was, however, considered to have "tumbled down from above," and so was passed by. In 1888 Mr Abbott saw a tusk taken out of the gravel in the course of excavations for a wharf in Upper Thames-street, it was associated with bones of pachyderms. Although he felt sure of its identity, he was unable to procure the specimen, probably because his eagerness to obtain it manifested itself to the workman, who immediately affected that he would not part with it. Not long afterwards, in an excavation between Leadenhall and Fenchurch streets a number of bones were taken out of the gravel which underlies the peat, which in turn underlies the Roman layer. The upper part of the gravel is stained somewhat by the peat, as are the contained bones. Amongst the latter there was a large part of the skull of a walrus, with one tooth still left *in situ*, the others having been destroyed in the rough usage to which it had been submitted in bygone times. The state of preservation is seen to be exactly similar to that of the other bones found with it, while its position, Mr Abbott thinks, leaves no question as to its Pleistocene age. He holds therefore that in future *Trichechus rosmarus* should be added to the Thames valley fauna.

AT the meeting of the chemical section of the Franklin Institute on October 18, Mr. Palmer read a note on a lilac colour from extract of chestnut. He said that in experimenting with a commercial extract of chestnut wood, with the idea of making galloflavine therefrom, he had obtained an unlooked-for result. The extract was somewhat fermented; that is a part of the tannin had been changed into gallic acid; and the

design was to convert this gallic acid into galloflavine by the usual method. A solution of the 51" extract was made strongly alkaline with potash, and subjected to the action of a stream of air for about ten hours. The temperature, meantime, was kept below 50° F. At the end of the period of oxidation the potash was neutralized with acetic acid. The solution so obtained was tested for galloflavine by working therein cotton and wool yarns with the addition of potash alum. While no yellow colour was obtained, a clear, bright lilac was developed on both the animal and the vegetable fibre. The body giving this colour has not as yet been separated from the oxidized extract.

A BOOK entitled "Mind and Matter: an Argument on Theism," by the Rev James Tait, of Montreal, has been so well received that a third edition, revised and enlarged, has just been issued (London: C. Griffin and Co.). Whatever may be said of Mr Tait's theology, he has a good deal to learn as to the temper in which the consideration of scientific problems should be approached. It seems a little foolish, at this time of day, to talk about the "horrible plautus" which "have accompanied every effort to establish man's brutal descent."

A PAPER embodying various suggestions to travellers was read at the June meeting of the Queensland branch of the Royal Geographical Society of Australasia by Mr J P Thomson, the honorary secretary of the Society. The paper, revised and enlarged, has now been reprinted from the Society's "Proceedings and Transactions."

THE Society for Promoting Christian Knowledge has issued a new edition of "Sinai from the Fourth Egyptian Dynasty to the Present Day," by the late Major H S Palmer. The little book has been revised throughout by Prof Sayce.

MESSRS. NEWTON & CO have issued a catalogue of science lanterns, magic lanterns, dissolving view apparatus, and lantern slides, manufactured and sold by them. The catalogue is accompanied by a supplementary list for season 1892-93.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista* ♂) from West Africa, presented by Mr W H Henniker, two Great Kangaroos (*Macropus giganteus* ♀♀) from Australia, presented by Sir Francis Wyatt Truscott, J P., F Z S, a Common Chameleon (*Chameleon vulgaris*) from North Africa, presented by Miss Truefitt, a Sykes's Monkey (*Cercopithecus albigularis* ♀) from West Africa, deposited.

### OUR ASTRONOMICAL COLUMN

COMET HOLMES (NOVEMBER 6, 1892).—Computations of the orbit of this comet show now that it is an elliptic one, the period extending to 678 years, very nearly the same as that of Wolf Comet, 1884 III—1891 II. The time of perihelion occurred on June 20 7357 of this year, and the comet's orbit may be mentioned as lying wholly between those of the planets Jupiter and Mars.

The following elements and ephemeris are due to Mr. A. Berberich, and are derived from observations made on November 9 (Karlsruhe), November 18 (Hamburg), and November 25 (Berlin).—

A NEW COMET (BROOKS, NOVEMBER 20) — On the evening of November 20 a telegram was received at Kiel announcing the discovery of a new comet by Brooks on November 20. Its position on November 20 875, Greenwich M T was given as R A 12h 57m 40s, Decl +13° 25'. Its physical appearance was described as "circular, diameter equal to 1', brighter than a third magnitude star, some eccentric condensation, no tail."

From observations made on November 21, 24, and 26, Prof Kreutz has found the following elements and ephemeris, which has been communicated by a Kiel circular post-card —

A NEW COMET — The comet which on the 24th was discovered by Mr Freeman is now supposed most probably to be a nebula.

THE CHANNELS OF MARS — In our Astronomical Column for November 17 we referred to the most recent hypothesis that had been put forward with respect to the doubling of the channels on the surface of Mars. Another suggestion has lately come under our notice, and this, although explaining the phenomena in quite a different way, has a point or two in its favour. This explanation appeared in the *Shanghai Mercury* on October 14, and was written by Mr T W Kingsmill, the following being a brief summary of the main points —

As Mars revolves round the sun, under the rule of gravitation, she must have tides on her surface, and since her moons are not sufficiently large to cause any sensible rise, her tides must be mostly solar. Now the best views we have of this planet is when he is in opposition, that is when we are interposed between him and the sun, so that we should always see him best at high tide. The writer then makes rather a strong point of the great eccentricity of the orbit of Mars, and the consequent heavy fall which he makes when plunging towards the sun. Situated further from the sun than we are, Mars of course must be reckoned as an older member of our system, and since he is smaller than our earth, it is only natural that his surface crust would be thicker than ours. Granting this then the internal pulp would not have such a power to compensate for this rapid fall, as our earth does internally, for there would not be much of it, so that an external compensation, assuming the crust to be too thick to alter its form, would have to take place at the surface. On the surface of course the water is the only available power, therefore we should expect, to put it in Mr Kingsmill's own words, "that the water in the ocean would be projected into the Martial hemispheres, and as the planet approached the sun, solar tides would sweep round the planet, that the canals should sometimes appear and sometimes be duplicated. . . . is only what *a priori* might be anticipated."

Those interested in this question will be glad to hear that M Stanislas Meunier (*Comptes rendus* for November 21, No. 21) has been continuing his experiments on this subject, which we referred to a fortnight ago. He finds now that by employing a metallic sphere instead of a polished mirror, and covering its surface with the veil as he did his former experiments the

results are more striking, and bring out more clearly the phenomena really observed on the planet's surface.

ASTRONOMY AND ASIOPHYSICS — The November number of *Astronomy and Astrophysics*, among many of its interesting articles contains one by Prof Pickering on the lunar atmosphere, which will be read with much interest. Accompanying the article is an illustration of the recent occultation of Jupiter, at which time a dark band tangent to the moon's surface but on the planet was both observed and photographed. Prof Coakley writes on the "Probable origin of Meteorites," the conclusions which he draws referring their origin to prehistoric lunar eruptions.

Prof. Hale, in addition to several articles on solar physics, describes generally the proposed new giant Chicago refractor, and from all accounts the observatory when finished and ready for work will be operated by simply pressing buttons, the observing chair will be entirely eliminated, the floor of the observatory, capable of motion in the vertical direction, serving the purpose. Mr W W Campbell gives rather a lengthy account of his observations on the spectrum of the late Nova, and the result may be summed up in the words, "While the hypothesis of two bodies quite generally satisfies the observations, and has the further very great advantage of simplicity, there are a few not unimportant points furnished by the photographs which favour the existence of three or four bodies, two or three yielding bright line spectra and one a dark line spectrum."

A NEW OBSERVATORY — M S de Glasenapp recently announced to the French Academy of Sciences that a new astronomical observatory has been erected at Abastouman, in the government of Tiflis. The observatory has been called Géorgioskaja, in honour of its founder, and it is situated at a height of 1393 metres above the level of the sea, its terrestrial co-ordinates being latitude + 41° 45' 43" longitude, east of Paris 2h 41m 58s. At present it is provisionally supplied with a refractor of about nine inches belonging to the St Petersburg University. Work has already been begun, and from all accounts the situation seems to be most favourable, many double stars measures having been obtained, which in ordinary circumstances are accounted very difficult objects with such an aperture. The observatory was opened on August 23 of this year, and up to November 5 as many as 400 double stars have been measured, omitting observations of the total lunar eclipse and of some phenomena of Jupiter's satellites.

#### GEOGRAPHICAL NOTES.

DR KARL DIENER has returned to Vienna from his geological expedition in the Himalayas, which has resulted in important additions to the data available for a geological description of the great mountain system. In June the expedition commenced work in North Kumaon, crossing the Utadurra Pass (17,600 feet), and after more than three months spent amongst the border ranges of Tibet, returned to India by the valley of Alaknanda. For a month the party never camped at a less height than 14,500 feet, and the highest summit reached was over 19,000 feet.

DR NANSEN is threatened with a serious rival in Lieutenant Peary, who has obtained leave from the United States Navy for three years to be spent in Arctic exploration. The base of his projected journey would be the farthest point reached by him on his recent journey in Greenland, and "an incidental object" would be to reach the pole by travelling over the frozen surface of the sea which he believes to surround it.

FRIEDRICH HELLER VON HELLWALD, well known as a writer on geography and ethnology, died on November 1, aged fifty years. He was born at Padua, and grew up with an equal knowledge of German and Italian, a fact to which much of his ultimate success as an author may have been due. He was an officer in the Austrian army, but devoted most of his time to historical research and literary work. His earliest work, "Amerikanische Völkerwanderung," appeared when he was twenty-four years of age, and later he wrote on the Russians in Central Asia, the native people of various parts of Asia, the history of civilization, and other subjects. His "Die Erde und ihre Völker" formed the basis of Stanford's "Compendium of Geography and Travel." For many years Hellwald edited the geographical journal *Das Ausland*.

CAPTAIN H. L. GALLWEY, vice-consul for the Oil Rivers Protectorate, gave, at the meeting of the Royal Geographical Society on Monday, a detailed account of his travels in the Benin country, of which notice has already been taken in this column (vol. xlv. p. 65). The fact that some of the deltaic streams are clear and transparent, while the Niger water is very muddy, makes it probable that they are small independent rivers. An account of a visit to Benin city gives some idea of the decadence of native West Africa since the time of the early writers on the region, if these were to be trusted.

MR. F. WILKINSON read a paper on the Kalahari desert, at the same meeting. It described a waggon drive through part of the desert area in company with two others, whose names were disguised under initials. Although great scarcity of surface-water was found, and the draught oxen and horses had sometimes to be watered from "sucking holes," where natives sucked up the water and filled the buckets from their mouths, the land was fairly well grassed in most parts, and Mr. Wilkinson believes it possible that it may subsequently become useful for grazing. A rough geological survey of the district passed over was made. Granite covered a large part of the surface, and appears to be the bed rock of the whole district examined. Hard crystalline siliceo-calcareous beds and highly altered ferruginous shales, as well as quartzite were also found, but vast accumulations of blown sand masked the true geological structure in almost every place.

THE Geographical Society of California claims to have achieved "an immense success." The Society was incorporated on December 11, 1891, for "the acquisition and dissemination of scientific geographical knowledge," and has already achieved a membership of 400. Monthly lectures have been given, and a bulletin has been published. We hope that a society which has begun so well will fulfil the Latin proverb which it has adopted for its motto, "*Vires acquirit eundo*."

### THE ANNIVERSARY DINNER OF THE ROYAL SOCIETY

THE anniversary dinner of the Royal Society was held on the evening of St. Andrew's Day at the Hôtel Metropole. It was more largely attended than any previous anniversary dinner, covers being laid for about 230. The chair was occupied by the President, Lord Kelvin. On his right were Mr. Shaw Lefevre, M.P., Sir James Paget, the Italian Ambassador, Prof. Raoult (medallist), Sir H. R. Cooke, M.P., Sir James Lister, Lord Justice Lindley, Sir B. Samuelson, Sir A. Moncrieff, Sir U. Kay-Shuttleworth, M.P., Sir C. E. Bernard, the Dean of St. Paul's, Mr. John Hutton, and Sir H. Acland. On the left of the chair were Mr. Arthur Acland M.P., Prof. Huxley, Mr. James Bryce, M.P., the Swedish Minister, Lord Ashbourne, Sir G. Stokes, the Treasurer of the Society (Sir John Evans), Mr. Alma Tadema, Sir R. E. Welby, Mr. Herbert Gardner, M.P., Sir Geoffrey Lushington, Mr. Bryant, and Dr. Mackenzie. The vice-chairs were occupied by Sir B. Baker, Prof. Roberts Austen, Lord Rayleigh, Prof. M. Foster, Sir A. Geikie, Mr. Norman Lockyer, Dr. Pye-Smith, Prof. Viner, and Mr. Rix (assistant secretary). The first toasts were "The Queen and the Prince and Princess of Wales," and "Her Majesty's Ministers and the Members of the Legislature."

Mr. Shaw Lefevre, in the course of his reply to the latter, said that men of science as a rule were unwilling to abandon the quiet fields of research in order to launch on the stormy seas of politics, and if they were willing, they were too philosophical to swallow the creeds of either political party. He thought that the two older Universities might help in this matter, and do more to justify their right of representation by emulating the example of the London University in returning men of science to Parliament. If there was any man in the country whose presence in the House of Commons would add to its quality and power, it was Prof. Huxley.

Mr. Acland, in proposing the next toast, said,—"I have to propose to those who are here present, and who do not bear the title of "F.R.S.," the toast of "The Royal Society"—a society ancient, independent, distinguished, and most beneficent in its operations during a course of more than two centuries. Why I, a mere politician, have been selected to propose this toast I do not know. In looking over a list of the late proceedings of your society a day or two ago, I tried to discover some links between yourselves and the Education Department, over

which I preside. I came across the words, "On character and behaviour," and I thought that that looked like the kind of language which we employ in our instructions to her Majesty's inspectors of schools. But it was not so. The subject to which the words had reference was "on the character and behaviour of the wandering cells of the frog, especially in relation to micro-organisms." I feel that I must fall back upon some more substantial links than that, and I fall back upon the fact that I have the honour to preside over certain institutions in which members of your society are engaged. There is the Dean of the Royal College of Science at Kensington, Prof. Huxley, and your foreign secretary, Sir Archibald Geikie, and, altogether, including those who examine for us from time to time, there are something like thirty members of the Royal Society who are connected with those institutions, and I consider it a very high honour to be linked with institutions with which they are connected. Whether some of my friends at Kensington look on their connection with the State in the same light, I do not know. When I have the honour of going over the laboratories of my friends, Prof. Thorpe and Prof. Rucker, I am inclined to doubt it. But as far as the present connection with the State goes, the Royal Society do most admirable service. They act as unpaid judges for the administration of a sum of £4,000, which the State would find it very difficult to administer on its own account, and they do the work in so impartial and admirable a manner that no man in his senses could complain. There is one other link between us. There are present here a large number of men who are interested in the work of education, and I think they will agree with me that we have one great task before us. Between the Universities and the University Colleges with which most of them are connected and the great sphere of elementary education there lies a large region, at present unorganized and chaotic, which we want to organize and bring into working order as soon as possible. There are many men of science in these colleges who often greatly regret to find willing lads, with the highest scientific capacity, brought under their notice and care, whose only lack is a lack of adequate educational preparation for their work. It is that which we want to remedy, and if I am enabled to take however humble a share in remedying it, I shall be proud of the task. We want to engage in the task of the reclamation of waste, and one of the most serious of all wastes is the waste of intellect. For those lads who go to our colleges in every part of Great Britain and Ireland we want to hold out one great possible goal—the blue riband of science—the title of Fellow of the Royal Society. You at any rate in your scientific honours have no distinction of class, and, as your medallists to day will testify, no distinction between one country and another. You regard all as equal when you adjudge your honours to the fittest men to bear them. I connect with this toast the name of your distinguished President, Lord Kelvin. It was truly said some nine years ago, when his claims were urged for the Copley Medal, "there is scarcely a branch of physical science to the substantive advantage of which he has not contributed," and I understand that while he has touched both the highest and the most abstruse subjects, he has not failed to condescend even to humble matters like the domestic water tap. Among those of you who know far better than I do what Lord Kelvin has done, both for abstruse science and for the welfare of mankind, there can be no limit as to the value of his work to future generations. I am sure that he himself cannot possibly say how great the value of what he has done may be in the far-off future. But I understand from Sir Archibald Geikie that your president has attempted to put a limit to the inquiries of the geologists, when they look into the backward past. He has definitely said that in looking backwards they must not go beyond the moderate limit of twenty million years. I understand that this is a grievance on the part of the geologists, but I hope that the President will not give unnecessary pain to his geological friends. In the draft of the preamble of your charter—it was drafted by Sir Christopher Wren—it was said Fellows of the Royal Society, by "their labours in the disquisition of nature, would try to prove themselves real benefactors of mankind." I give you the toast of "The Royal Society," coupled with the name of Lord Kelvin, and I assert that your present President has done his part in proving himself a benefactor of mankind.

The Chairman, in replying, said,—"I thank you very heartily for the kind manner in which you have received this toast. I feel the honour you do me, but I also feel my incapacity to say

what ought to be said for so great an institution. I can only say in my own way that I believe the Royal Society, as an institution, has up to the present time persevered in well doing, and had been successful in its efforts. The Royal Society has certainly endeavoured to carry out the objects of its institution—namely, to inquire into natural knowledge and the improvement of it. The mode of carrying out that object was carefully considered, no doubt, by those who founded the Royal Society, and they determined to hold regular meetings, partaking somewhat of the character of a debating society—meetings where discussions could be raised by questions presented, and the truth arrived at thereby. That object has been carried out from the inception of the Society to the present day, and the society has been imitated by other societies over a large part of the civilized world. Indeed, the Royal Society itself only followed in the path of other learned societies in Italy, which had determined that by personal discussion of questions in regular meetings truth might be arrived at which otherwise might be lost. We often find complaints that meetings of scientific societies are unsatisfactory. We have even complaints that the important duty, the publication of their proceedings for the rest of the world, is not altogether ideally perfect. Some who desire the progress of science above all, and heartily wish success to the Royal Society, think that the society ought to be a body for merely recording and indexing the work that has been done all over the world. That is a part of the work of the Royal Society which is not neglected. The council has had most anxious, careful, and laborious consultations from year to year with reference to this work—not only as to the publication of its own transactions and proceedings, but as to the cataloguing and indexing of the proceedings of scientific bodies and scientific workers all over the world. One very important part of the work of the society consists of the cataloguing of all scientific papers published, and a very dry and fatiguing subject it is to work upon. The difficulty here is *embarras de richesses*. To get the titles only of these papers is itself a truly Herculean task. If the Royal Society had not only capacity, but had also great funds at its disposal, it would make short work of this task. It would not only index, it would publish the papers, and would put them in such a form that any one could find his own particular subject at once, and the particular volume and page in which it was treated. This is an exceedingly difficult subject, but the first necessity is funds, and if those were supplied all the rest would follow. The publishing and indexing, however, is not the only work of the society. The life and soul of its work is in its meetings and discussions, and whoever has not felt the stimulus of attending those meetings has hardly yet found out the spirit of scientific enquiry. For myself, I say the fact that we can attend meetings of the Royal Society, and hear papers on subjects very far removed from the subjects of our every day work, is a stimulus which is of the highest value. The worker who has heard what other people are doing goes back to his work with something which may help him in it, which, at any rate, brightens his life, and makes the drudgery and heavy work necessary for success in any scientific investigation less irksome and dry. For myself I may say that my connexion with the Royal Society, extending over a great many years, has been one of unmixed benefit and pleasure, and has given to me some of the happiest of those pictures of knowledge and memory the possession of which constitutes so much of the delight of life. Mr Acland remarked upon my having been hard upon the geologists. I do not think that I have actually been so. I do not believe in one science for the mathematician, another for the chemist, another for the physicist, and another for the geologist. All science is one science, and any part of science which places itself outside the pale of the other sciences ceases for the time being to be a science. The sooner it returns to the pale of the other sciences the better, and when all are working for a common good the better it will be for the progress of each.

Prof. Huxley, in proposing the next toast, said that he had to discourse on the merits of the gentlemen to whom medals had been awarded. There was one adequate treatment of whose merits would occupy the whole available time, and yet Mr Shaw Lefevre wished him to say something about his capacity to become a legislator and also to give an opinion upon geological time. He would answer the first interrogation by telling a story. When he was a very young man a solicitor in large practice discovered in him what that gentleman believed qualities that would command success at the Bar, which he had never discovered

himself, and proposed to advance him an income for a certain number of years until he could pay the amount back out of the fees he was sure to earn. He was sorry to say his reply was this, "So far as I understand myself, my faculties are so entirely confined to the discovery of truth that I have no sort of power of obscuring it." With regard to political life, the absolute contradictions that were made by politicians of opposite sides upon matters of fact were absolutely fatal to his chances in a political career. Coming to the subject of the toast, he narrated the history of the Copley medal. A bequest of £100 was left to the Society 188 years ago by Godfrey Copley, a Fellow of the Society, for improving natural knowledge. The medal was thrown open to all the world, a step much disapproved by certain narrow-minded persons at the time, but that step was the real reason why, a century later, Sir Humphry Davy could really call it "the ancient olive crown of the society." The value of the medal was originally fixed at £5, people being able to get five per cent for their money in those halcyon days. He did not like to dwell upon its appreciation now lest the County Council should put in a claim for unearned increment. The medal had certainly done nothing for itself, the appreciation of its value had arisen entirely from surrounding circumstances, the chief being the wisdom and integrity of some eighty successive councils. A complete list of the awards was published every year. Going back one hundred years from 1887—he had a reason for not taking a later date—the century began with John Hunter, and finished with Joseph Hooker. Between them was a galaxy of the heroes of science, French, German, Scandinavian, Italian, American, and English, and, although one star might differ from another star in glory, none was unworthy of its place in the constellation. The present council had not fallen below the standard of its predecessors, there was no biologist, no scientific physician, no anthropologist, no archaeologist to whom the name of the illustrious Rector of the University of Berlin, Rudolph Virchow, was not familiar. No one had done more to put pathology on a scientific foundation, no one had done more for critical anthropology, especially in connection with archaeology. Without venturing on the dangerous field of politics, he would add that these merits were, to his mind, greatly enhanced by the fact that Virchow had never merged the citizen in the philosopher, but amidst great difficulties and with undaunted courage, he had taken an active, a disinterested, and a thoroughly independent course in the Legislature of his country. The next medal in order of age was that founded by Count Rumford at the commencement of this century, on equally cosmopolitan principles, but limited in scope to the physico-chemical sciences. In these sciences hardly anything had attracted popular attention more of recent years than the marvellous power which spectroscopy had placed in our hands to discern the chemical composition of bodies which were millions and billions of miles away, and, for anything we knew to the contrary, these minute and careful inquiries into the constitution of stars might be *post-mortem* examinations. In the accurate examination of stars by the spectroscope, he understood from others that Dr Dunér, of Sweden, had laid secure foundations for all future investigations. The Royal medals were founded by the Sovereign some sixty-odd years ago, were now maintained by her Majesty, and were confined to British subjects. There were two medals every year, and they were usually allotted one to physical and chemical science, and the other to biological science. They were usually given to younger men; and it was so in his own case forty years ago. The value of the medal was inexpressible to him. In his younger days, if a man took to science, it was thought he was going to the bad. The receipt of the medal made an entire revolution in the minds of his friends, and he was a respectable person from that time. On the present occasion the first of these medals was awarded to the present Director of the Astronomical Observatory in Oxford, Prof. Pritchard, and he was told that there was no observatory in the three kingdoms in which so much admirable work of observation was being done. Only a short time ago the Royal Astronomical Society awarded its gold medal to the Director of the Oxford Observatory. He was further told that the director was tackling what he understood was one of the most difficult pieces of astronomical work—parallax determination; and that he had already printed off more stars than anybody else. Besides this, he was hard at work on the great international chart of the heavens. It was obvious that this gentleman must be in the

full vigour of youthful energy, and therefore he treated with contempt a rumour that had reached him that the director was in his eighty-fourth year. They would join with him in wishing Prof. Pritchard a long continuance of the health and strength which were turned to such splendid account. The second of these medals was awarded to Dr. Langley, of the University of Cambridge, for the long-continued and very valuable physiological researches. There was a familiar phenomenon observable before sitting down to dinner, and known as watering of the mouth. If it were possible to determine the exact condition of that operation in physiology the exact knowledge would be a key to an immense range of the secrets of Nature. It was these problems that Dr. Langley had been investigating, and he had come nearer to their solution than any one else. The Davy medal was awarded to a distinguished French *savant*, M. Raoult, whose work was considered of the highest importance, and he rejoiced that the recipient of the medal was present. The Darwin medal was instituted in honour of one of his best and dearest friends, and it was now conferred upon a man who was one of the staunchest friends he had had for the last forty years. He might fairly appeal to Sir Joseph Hooker's present activity, put him down also among the young men, and thereby save the credit of the council in the matter of its own regulation. To those who knew the "Life and Letters of Darwin," talk about Sir Joseph Hooker's right to the Darwin medal was as futile as the attempt to judge Manlius in sight of the Capitol. He knew no more remarkable example of life long devotion, of stores of information laid open, of useful criticism, and of still more useful encouragement, by one man to another, than that exhibited by Sir Joseph Hooker in this picture. It might be that even the man whose motto was "It's dogged as does it," and who so patiently laboured for half a lifetime at the great fabric of the origin of species, might have fainted by the way without this friend's aid. And assuredly Hooker's great study of geographical distribution was a most important factor in Darwin's work. It lay in the eternal fitness of things that Wallace and Hooker should receive the Darwin medal, and that these old young men should give it a heightened value for the young young men to whom it would hereafter pass.

Prof. Raoult returned thanks, speaking in French.

Dr. Langley responded for the other medallists and himself.

Sir James Paget briefly proposed "The Guests."

The Swedish Minister, in responding, said—"The honour to be your guest and to participate with you in the celebration of this interesting day cannot be more thankfully felt than by me, who still has to consider this favour, above all, as a compliment to the country where you have selected this year your Rumford medallist. This distinction to my fellow-countryman, Prof. Daner, whose merits Prof. Huxley has so eloquently explained to you, is a new link in the long chain of tokens of sympathy and appreciation from this society to scientific Scandinavians, a chain of which one of the oldest links is the creation of the Linnæan Society. More than a hundred years have passed since, and in the meantime many systems have been altered, and, especially in the last twenty years, those alterations have so closely followed the one upon the other that we laymen have been accustomed to believe we were entitled to ask every new morning, "What great discovery will this day bring?" In one department, however, scientific men as well as laymen cannot admit the possibility of any alteration, and that is in our conviction and belief that this country occupies a prominent place in the universal scientific movement—a proof of which, among many others, is the fact that no other institution in the world encourages as much as does this society other countries' scientific researches."

Mr. Alma-Tadema also responded, remarking in the course of his speech that there was no art without science, neither was there any science without art, and that art coloured life as the sun colours the flowers of nature.

### AZOIMIDE

A FURTHER communication concerning azoimide, the interesting compound of hydrogen and nitrogen,  $N_2H$ , discovered two years ago by Prof. Curtius, is contributed to the current number of the *Berichte* by Drs. Noeltling and Grandmougin of Mulhausen, in conjunction with Herr O. Michel. As described in our note of vol. xiv. p. 600, Drs. Noeltling and Grandmougin have previously shown that azoimide may be obtained by indirect means

from the singular compound prepared somewhere about the year 1866 by the late Dr. Peter Griess, and which has hitherto been

known as diazobenzene imide,  $C_6H_5-N \begin{smallmatrix} \diagup N \\ \diagdown N \end{smallmatrix}$ . This com-

compound is now recognised as the phenyl ester of azoimide. It is, however, a substance of very considerable stability, and successfully resists the attack of concentrated alcoholic potash, even under pressure. Although thus stoutly resisting direct attack, Drs. Noeltling and Grandmougin have shown that by undermining its constitution by the introduction of a couple of nitro groups in the place of two hydrogen atoms, it becomes weakened so greatly as to be no longer capable of withstanding the action of the alkali, and is decomposed with production of the potassium salts of azoimide and dinitro phenol—

This interesting result is now supplemented by showing that it is not necessary to introduce two nitro groups in order to render diazobenzene imide sufficiently negative in character as to be susceptible to the attack of alcoholic potash, that one such group suffices, provided it be introduced in the para or ortho position. A nitro group introduced in the meta position appears to exert much less weakening power, quite inadequate for the purpose

Para nitro diazobenzene imide, , is a substance crystalliz-

ing well in colourless tabular crystals. When these crystals are allowed to fall slowly into a cold solution of one part of caustic potash in ten parts of absolute alcohol, they instantly dissolve and the liquid becomes coloured a deep red. If this red solution is warmed for a couple of days over a water bath, and the larger portion of the alcohol subsequently distilled off, upon acidification of the residue with dilute sulphuric acid, and again distilling, azoimide,  $N_2H$ , passes over along with the vapour of water and alcohol. In order to free the azoimide from alcohol it is only necessary to neutralize the distillate with soda, and evaporate the solution to dryness, when the sodium salt of azoimide,  $N_2Na$ , is obtained, the sodium salt is then dissolved in water, the solution acidified with sulphuric acid, and subjected to distillation, when an aqueous solution of azoimide is obtained. The yield of azoimide is usually only about 40 per cent. of the theoretical, owing to secondary reactions which occur simultaneously with the main one. The ortho compound,

 treated in a similar manner, also furnishes azoimide

to the extent of about 30 per cent. A very much larger yield, about 85 per cent., is afforded by the dibrom derivative of

the para compound, Br  Br, a substance which is readily

obtained in the form of long colourless prisms. Azoimide has also been obtained to the extent of 30 per cent. of the theoretical amount by the decomposition of a nitro toluene derivative of

azoimide of the constitution 

# THE NEW STAR IN THE CONSTELLATION OF AURIGA<sup>1</sup>

THE appearances which the new star has presented were exceedingly remarkable, and observations, both spectroscopic and photometric, were far more numerous than have been obtained during former occurrences of this kind. The latter have been sufficient to establish the unsuitability of several explanations which have been suggested with regard to former new stars, suggestions which at the time appeared more or less plausible. On the other hand, however, it is very difficult to establish, from the publications of observers up to the present time, all details required for a general proof of a definite hypothesis. It appears to me appropriate to suggest a new attempt at explanation, which seems to tally better than others with the principal results of observation, the final tests of which hypothesis must, however, for the present remain a matter for the future. But if this attempt should in the present instance meet with difficulties—a case which I admit to be possible, if not probable—it yet deserves a somewhat more detailed explanation, because it thoroughly takes account of, as I believe, possible conditions, and therefore certainly contains a possible hypothesis with regard to the appearances of certain new stars. In the following remarks I shall strictly adhere to the facts which are to be considered, according to the statements of the observers, as the result of their observations, whereas a proof of the latter is beyond the limit of this article. I may here mention that I have already suggested the most essential of the following remarks in March of the present year.<sup>2</sup>

The chief results of observations, which may be said to contain the characteristics of all the appearances, are —

1 According to Herrn Lindeman<sup>3</sup> the light curve of the Nova presented the following appearances —

"From February 1 to 3 the photometric curve rises quickly to a brightness of 4<sup>m</sup>, then gradually sinks till February 13, and then quicker until February 16 to 5<sup>m</sup>, reaches a second maximum of 5<sup>m</sup> 14<sup>m</sup> on February 18, has a second minimum on February 23, likewise of 5<sup>m</sup>, and then a third maximum on March 2 again of 5<sup>m</sup>, upon which it sinks till March 6, slowly at first, and then quicker, in a straight line till March 22 down to 9<sup>m</sup>." I may here add that from the photographs taken at Harvard College, it was possible to show that the star became visible from the beginning of December, 1891, that already in the period of time December 20-22 it showed a maximum of brightness which reached almost, but apparently not entirely, a maximum on February 3.

2 The spectrum of the Nova was most remarkable. Prof. Vogel, in summing up the results obtained at Potsdam,<sup>4</sup> writes —

"The observations have led to the exceedingly interesting result that the spectrum of the Nova consists of two superposed spectra, and that a number of lines, especially those of hydrogen, which appear bright in one spectrum and dark in the other, are closely adjacent to one another. This fact admits of hardly any other explanation than the presence of two bodies, the component motions of which in the line of sight are very considerable. The bodies separate from one another with a relative velocity which during four weeks' observations (in February) suffered no appreciable change, and which amounted to at least 120 miles per second." It may be further added<sup>5</sup> that among the very broadened bright lines there were noted several intensity maxima, two being especially striking.

It has been suggested as an explanation of the facts of observation that two heavenly bodies have passed very close by one another, and that thus changes in their atmospheres have arisen which have caused the sudden brightening up of the bodies. The above hypothesis is, however, in this form too vague to be followed in detail. In reverting to an idea of Klinkerfues, it is true that a more distinct picture of the whole occurrence has been drawn, by assuming tidal effects of the two bodies upon each other in this manner where the tidal crests of the atmosphere appear, there the darkenings take place by absorption, and where the ebb predominates a brightening is the result,

because here the absorbing strata of the atmospheres are less powerful. It must be mentioned, however, that the statical theory of Ebb and Flow that has been applied is altogether inappropriate to give an idea of the deformations which doubtless occur at such a near proximity. The effect of the two heavenly bodies on each other in Nova Aurigæ, as is still to be shown, would have to be one that is almost always suddenly appearing and immediately afterwards vanishing. Moreover it must not be overlooked, that with incandescent bodies their atmospheres must be regarded as outward shells which quite gradually emerge into denser strata, while these also are deformed in a lesser degree. In other respects, too, it will be difficult to explain the appearances of a new star as a consequence only of the effects of absorption of atmospheres. It has also been assumed for the most part that besides these (absorptions), eruptions of gas from the centre of the body take place. This assumption, it is true, contains nothing impossible, but without a definite form it hardly admits of discussion. At all events it will be necessary to suggest further hypotheses in order to apply this attempt at explanation to single cases. Moreover, it remains yet unexplained why in Nova Aurigæ the one spectrum is chiefly an absorption spectrum and the other a gas spectrum. By special assumptions this difficulty can be certainly eliminated, but it is not very probable that on this account confidence can be placed in the correctness of the hypothesis.

Other facts appear, however, in the case of Nova Aurigæ which do not speak in favour of this hypothesis, however generally it may be expressed. It is at least very striking that just in this case such enormously great velocities of cosmical bodies appear, such as have hitherto not been found anywhere else. The occurrences of these velocities must therefore be numbered among the facts to be explained. Further on formulæ will be given from which, at least to a certain degree, the mechanical conditions of the close approach of two bodies can be computed. From this it follows that in the case of Nova Aurigæ the two bodies can describe a parabola round each other only if their masses are much larger than 15,000 times the sun's mass. For a hyperbolic movement one can obtain an essentially smaller value of the mass, by assuming that the enormous relative velocity of 120 miles observed has been reduced to a small degree by attraction and has existed almost entirely from the beginning. Thus the choice is left between the assumption of extremely large masses or the giving up of an explanation of the great relative velocity. Neither of these two assumptions contain, it is true, an impossibility, but I do not think that doubtful proofs for the correction of the hypothesis can be noticed in either of them. According to my opinion they rather render it (the hypothesis) very little plausible.

The formulæ already mentioned indicate what will be explained further on, namely, that the supposed effect of the two bodies, in the case in hand, must have taken place very quickly indeed, perhaps even in the period of a few hours. This effect must necessarily have occurred upon the first brightening up (beginning of December 1891). Why then the Nova attained several weeks later (beginning of February 1892) a second maximum, and to all appearances a greater maximum, and why the light curve sank only very little till the beginning of March but afterwards very rapidly, seems to me, on the ground of the hypothesis in question, to be explainable only with great difficulty, if it can be explained at all. At all events, this difficulty will remain unless it be altogether removed in detail.

The difficulties hinted at above entirely disappear in the following supposition. There is no doubt, especially in accordance and with the results obtained from stellar photographs, in which Mr. Max Wolf has co-operated, that space is entirely filled with more or less extensive formations of very thinly scattered matter. With regard to their physical properties, these formations will probably show very varied constitutions, the reason for which we will leave an open question, as we do not wish to investigate it here. It is itself not very improbable that a heavenly body should get into such a cloud, but in any case it is more probable than the grazing together of two compact bodies, as is required in the above-discussed hypothesis. As soon now as the body commences to enter a cosmic cloud a surface heating will be set up at once, and indeed it must be so, whatever may be the constitution of the thinly-scattered matter. In consequence of this heating, the products of vapourisation will form round the body, these will partly be separated

<sup>1</sup> Translation of an article by H. Seelinger, in *Astronomische Nachrichten* (No. 3118).

from it and will adopt very quickly that velocity which the adjacent parts of the cloud possess.

It is interesting to compare this process with a similar one, which takes place in a well-known way in the appearance of shooting stars or fireballs. In this case a compact body enters with a certain velocity into a formation of very thin matter (the upper strata of the atmosphere), is heated and partly vapourized, and a luminous trail, which is clearly visible for a long time after the sudden appearance of the meteor, marks the path which the latter has taken. The detached particles have quickly lost their relative velocities against the air, for they apparently do not partake of the movement of the meteor.

If we consider spectroscopically the star on its commencement to become bright by resistance, two superposed spectra will openly reveal themselves, one in general continuous and provided with absorption bands in consequence of the heaping up of the glowing gases, and the other in the main consisting of bright lines. Both spectra, according to the relative motion in the line of sight, will appear pressed up against one another. Thus altogether an appearance is found very similar to that observed in Nova Aurigæ, and they will agree entirely if one assumes that also those parts of the cloud nearest the body have sustained physical perturbations by a direct frictional warning of the detached particles, &c. This assumption seems to me to contain by no means a difficulty considering our lack of knowledge with respect to the properties of this cloud matter. Whether this is at all necessary I am unable to say on the ground of the publications at hand.

The investigation is important to decide whether, on the lines laid out, we can obtain a plausible explanation of the great relative velocities shown by the two spectra. When the body approaches the cloud the latter will evidently lengthen itself in the direction of the former. This lengthening will grow with the mutual approach, just as the relative velocity of the single parts of the cloud will grow towards the body. Without certain suppositions on the structure of cloud matter it is difficult to conceive of the processes of movement which take place, so we must content ourselves with contemplating the one or the other case, which admits of a closer investigation.

If, for instance, we suppose that the single particles of the cloud follow for the main part the effect of the body, they will describe conic-sections—that is, hyperbolas round the centre of the latter as forces. Their greatest relative velocity decreases quickly with the distance of the body, so that the surroundings of the latter will be filled with particles moving with very different velocities. One can easily see that no very extraordinary assumptions are necessary to suppose very great velocities for these particles that pass near the surface of the body, velocities amounting to those stated in the case of Nova Aurigæ, even if they are at the outset very small. It follows from the above that the spectral lines of the particles which are moving from the body with such different velocities must be very much enlarged, and that to explain the different brightenings of the single parts of the lines as probably intensity maxima does not raise the least difficulty, but is a necessary accompanying phenomenon. This point seems to me to be important, for it cannot be deduced from the hypothesis of two compact masses passing close by one another, and must here lead to the rather improbable assumption of several moving bodies.

As long as the body remains in this, so to speak, atmospheric formation, the appearances above mentioned must always be called forth anew, whence it follows that the peculiarities of the spectrum conditioned by the whole state of things, not considering smaller perturbations, must on the whole remain constant for some time, a point which in the above hypothesis is at first not by any means clear. In a similar manner it will not be astonishing if the star during that time changes its brightness less strongly, while after its exit from the cloud this brightness will decrease rather rapidly. This too agrees with the light-curve in the case of the Nova. Finally, even the periodical fluctuations of the magnitude can be explained quite naturally. We call to mind here the well known fact confirmed lately by the photographs of Max Wolf, that similar occurrences appear in shooting stars, which may, indeed, be explained with difficulty.

We must, however, in any case assume that the star entered the cosmical cloud to question about the beginning of December and left it not long before the beginning of March. Now the question is urged upon us: How was it possible that for such a long

time the great relative velocity could remain constant though such a resistance must have taken place that could develop the heat necessary for the glowing of the body? We are here going to decide this question by comparing the resisting power of the star to that of a meteor in the upper strata of our atmosphere.

Let us assume, quite generally, that the motion of the star in a straight line is given by the equation

$$\frac{dv}{dt} = -\lambda v^n \quad (1)$$

(1) where  $v$  is the velocity,  $\lambda$  a positive number  $> 1$  and  $n$  a constant, which is directly proportional to the surface of the globular body and the density of the medium and inversely proportional to the mass of the body. We compare equation (1) with the equation for the motion of a meteor

$$\frac{dv'}{dt'} = -\lambda' v'^n$$

in which the time  $t'$  is referred to another unit selected for the purpose. If we suppose  $v' = \mu v$ ,  $t' = \nu t$ ,  $\lambda = \lambda' \mu^{n-1}$ . The latter equation becomes identical with (1), that is the movement of the star corresponds point to point with the motion of the meteor, if the latter equations are satisfied. Representing now  $m, O, r, \delta, m', O', r', \delta'$ , as masses, surfaces, radii, and densities of the star and meteor, and  $D$  and  $D'$  the density of the cosmical clouds and the upper strata of the atmosphere in question, we have —

$$\frac{\lambda}{\lambda'} = \frac{DOm'}{D'O'm} \cdot \nu \quad \mu^{n-1} = \frac{DOm'}{D'O'm}$$

or also

$$\nu = \frac{t}{t'} = \left(\frac{v}{v'}\right)^n = \frac{r' \delta' D}{r \delta D'}$$

If we put  $r = k$  times the sun's radius (= 700 million metres) and  $r' = r$  metres, and further corresponding to the observations of the new star  $\nu = 30$  (unit of velocity of Earth in its orbit) and  $t = 100$  days and  $v' = 2$  which corresponds to a relatively quickly moving meteor and finally  $n = 2$ , we have —

$$\nu = \frac{15}{k} \frac{D\delta'}{D'\delta} \frac{r'}{700 \text{ millions}}$$

and  $t' = 0.185 t$ ,  $f = \frac{r' \delta' D}{k \delta D'}$

Thus the movement of the star takes place proportionally in 100 days, just as that of the meteor in 18.5 seconds if we suppose  $f = 1$ . As we are free to assume  $\frac{D}{D'}$  small, we can obtain a

very small fraction of a second, and since within a hundredth part of a second the movement in the highest regions of our atmosphere shows no longer a perceptible decrease of velocity, such a decrease will not enter in the case of the star. We have evidently to deal here with the same appearance which points out that small heavy objects possess a far greater resistance to air than large ones, and that with large meteors (fireballs) the air resistance, as it has been proved, influences the elements of the orbit far less than is the case with small meteors.

We have still to show that in spite of the small decrease of movement, enough energy of movement is changed into heat in order to bring the star into a surface-glowing condition, and such a condition has by all means taken place in the Nova. We must therefore calculate the quantities of heat  $Q$  and  $Q'$  which is radiated in one second of time, and from a unit of surface on both bodies. If we call  $P$  and  $P'$  the losses in acting power during the times  $t$  and  $t'$ ,  $v_0$  and  $v'_0$  the velocities before the entrance into the resisting media, we have —

$$Q = \frac{P}{Ot}, \quad Q' = \frac{P'}{O't'}$$

$$\text{and } P = m(v_0^2 - v^2), \quad P' = m'(v_0'^2 - v'^2)$$

and taking into consideration the above equations

$$\frac{Q}{Q'} = \frac{D}{D'} \left(\frac{v}{v'}\right)^{n+1}$$

with the above numbers  $\frac{v}{v'} = 15$ ,  $n$  will be = 2

$$\frac{Q}{Q'} = 3375 \frac{D}{D'}$$

so that we can assume that the density of the cosmical medium, compared to those already very thin air strata, in which evidently

the glowing of the meteor occurs, is not very dense, and that one yet gets the necessary quantity of heat.

It may be remarked that we can vary all these numbers within very wide limits without fearing any contradiction, so that we may conclude, therefore, that no difficulty in the suggested hypothesis arises from this point of view.

I have now to deduce the formulae I have mentioned above, and it will be seen that these are very interesting.

If we take  $\mu$  as the sum of two masses revolving round each other in a conic section,  $V$  the velocity, and retaining for the rest the customary nomenclature, we have for the parabola

$$V^2 = k^2 \mu \frac{2}{r}, \quad r = \frac{q}{\cos^2 \frac{1}{2} v},$$

$$\tan \frac{1}{2} v + \frac{1}{2} \tan^2 \frac{1}{2} v = \frac{1}{q^{1/2}} \frac{\mu t}{\sqrt{t}}$$

Whence it follows without further difficulty

$$\mu = \frac{V^2}{4k^2 \sin^2 \frac{1}{2} v [1 - \cos^2 \frac{1}{2} v]}$$

One takes  $c$  as the velocity of the earth in its orbit with the radius  $R$  and puts the sun's mass and the mass of the earth = 1, so that  $k^2 = c^2 R$ . If we consider further that the expression

$$\sin^2 \frac{1}{2} v [1 - \cos^2 \frac{1}{2} v]$$

can attain the maximum value  $\frac{\sqrt{2}}{3}$  it follows that

$$\mu = \frac{3}{4\sqrt{2}} \left( \frac{V}{c} \right)^2 \frac{1}{R}$$

or if  $c$  be given in solar days

$$\mu = 0.00912 \left( \frac{V}{c} \right)^2 \quad (4)$$

To apply this to the Nova we must remember that  $\frac{V}{c} = 15$

because the orbital velocity may be greater than that in the line of sight. Besides, more than two months have passed since the supposed grazing of the bodies took place, which time must coincide closely with that of perihelion, up to the time that we have still spectrum observations in hand. Thus  $t$  is much greater than 60. Formula (4) —

$$\mu = 14779 \times \text{sun's mass}$$

gives thus a limit which supposes masses far too small. In reality we might perhaps assume double this without challenging contradiction.

The consideration of a hyperbolic movement takes a similar though less simple form.

If  $V_0$  represents the velocity at an infinitely large distance, we have

$$V^2 - V_0^2 = \frac{2k^2 \mu}{r},$$

and according to the Theoria Motus —

$$\frac{r}{a} = \frac{e - \cos F}{\cos^2 F},$$

$$e \tan F - \log \tan (45^\circ + 1/2 F) = \frac{k^2 \mu}{a^{1/2}} \frac{1}{V_0^2},$$

from which it is found at once that —

$$\mu = \left( 1 - \frac{V_0^2}{V^2} \right)^{1/2} \left( \frac{V}{c\sqrt{2}} \right)^2 \frac{1}{R} X \quad (5)$$

$$X = \left( \frac{e - \cos F}{\cos^2 F} \right)^{3/2} \cdot e \tan F - \log \tan (45^\circ + 1/2 F)$$

The expression for  $X$ , if one allows  $F$  to vary from  $0^\circ$  to  $90^\circ$ , first decreases, reaches a minimum, and then increases to infinity. The minimum value can easily be determined for then

$$\frac{3}{4} \frac{d \sin 2F}{(e - \cos F)^2} [e \tan F - \log \tan (45^\circ + 1/2 F)] \text{ must be } = 1$$

This equation can be easily solved for special values of  $e$ . For the theoretical calculation which is requisite, I have employed another proceeding, as I have already computed the serial values of  $X$  for a special value of  $e$ , as the following table shows: —

NO. 1206, VOL. 47]

	$e=1.5$	2.0	4.0	6.0	8.0	10.0
$F=4$	10 207	14 393	24 882	32 111	37 988	43 071
8	5 224	7 302	12 554	16 182	19 135	21 689
12	3 614	4 987	8 494	10 930	12 913	14 630

For very large values of  $e$  the minimum of  $X$  occurs if

$$\sin F = \sqrt{2/3},$$

and the minimum value of  $X$  becomes:

$$\text{Min } X = \sqrt{\frac{3}{2}} \frac{c}{2} = 1.612 \sqrt{c} \quad (6)$$

But one practically commits no error if one employs (6) also for the values of  $e$  nearly equal to 1, as is evident from the following computation of the minima values taken from the above table, and calculated according to formula (6)

$e$	Direct	Formula
1	1.5	1.6
1.5	1.9	2.0
2	2.2	2.3
4	3.2	3.2
6	3.9	3.9
8	4.5	4.6
10	5.1	5.1

One obtains —

$$\mu > 0.0104 \left( 1 - \frac{V_0^2}{V^2} \right)^{1/2} \left( \frac{V}{c} \right)^2 \sqrt{c} \quad (7)$$

For the above assumptions —

$$e = 0, \left( \frac{V}{c} \right) = 30,$$

we find

$$\mu > 16830 \sqrt{c} \left( 1 - \frac{V_0^2}{V^2} \right)^{1/2}$$

which formula holds good for values of  $c$ , which do not quite equal 1. In order to include also the parabola we suppose

$$\mu = 15000 \sqrt{c} \left( \frac{V^2 - V_0^2}{V^2} \right)^{1/2} \quad (7a)$$

Thus in this case we result in extremely large masses, which are not very probable, or we must assume that  $\frac{V_0^2}{V^2}$  is very nearly 1.

Even for  $\frac{V_0^2}{V^2} = 0.9$ , according to the above formula,  $\mu > 1200 \sqrt{c}$ ,

and we may consider the above given assertion as justified. It has already been remarked that this suggested inequality proves only that  $\mu$  is very much greater than the right side of the equation.

It is easy to find a higher limit for  $\mu$  if  $\frac{V_0^2}{V^2}$  does not differ much from unity.

If we put  $\frac{V^2 - V_0^2}{V^2 + V_0^2} = v$ , we obtain  $\cos F = v$ , and according to formula (5)

$$\mu = \left( \frac{1 - v^{1/2}}{1 + v^{1/2}} \right) \left( \frac{V}{c} \right)^2 \frac{1}{R} \cdot e \tan F - v \log \tan (45^\circ + 1/2 F)$$

Given  $t$ ,  $e$ , and  $v$ , we can calculate the right-hand side. But we seek, however, the maximum value of  $y = e v \tan F - v \log \tan (45^\circ + 1/2 F) = \sin F - v \log \tan (45^\circ + 1/2 F)$  by determining  $e$  as function of  $v$ . It is

$$\frac{\partial y}{\partial e} = \left( \cos F - \frac{v}{\cos F} \right) \frac{\partial F}{\partial e} = \frac{v(1 - v^2)}{e \sqrt{1 - v^2}}$$

Thus  $y$  increases so long as  $e < \frac{1}{\sqrt{v}}$ , and decreases continually for  $e > \frac{1}{\sqrt{v}}$ . The maximum for  $y$  takes place when  $e = \frac{1}{\sqrt{v}}$ , and is

$$y = \sqrt{1 - v} - v \log \left( 1 + \frac{\sqrt{1 - v}}{\sqrt{v}} \right)$$

Thus we have

$$\mu > \frac{c}{R} \left( \frac{V}{c} \right) \left( \frac{1 - v}{1 + v} \right)^{3/2} \frac{v}{\sqrt{1 - v} - v \log \left( 1 + \frac{\sqrt{1 - v}}{\sqrt{v}} \right)}, \quad (8)$$

and with  $\frac{V}{c} = 30$  and  $t = 60$  days,

$$\mu > 27800 \left( \frac{1 - v}{1 + v} \right)^{3/2} \frac{v}{\sqrt{1 - v} - v \log \left( 1 + \frac{\sqrt{1 - v}}{\sqrt{v}} \right)}$$

For the above example  $\frac{V_0}{V} = 0.9$  results  $\mu > 2800$  as considerably larger masses than formerly.

I have now further to prove that a very close proximity of the two bodies can have only taken place for a very short space of time. To do this we use the following relations.

We find above for the parabola

$$\mu = \frac{V^2 t}{4k^2 x}, \quad x = \sin \frac{1}{2} v (1 - 2/3 \sin^2 1/2 v)$$

It follows, therefore, that

$$V^2 = \frac{2k^2 \mu}{v} \\ r = \frac{Vt}{2x}$$

Thus we have

$$v > \frac{3}{2\sqrt{2}} \quad Vt = 1.06 Vt \quad (9)$$

For the hyperbola we have

$$r = \frac{2k^2 \mu}{V^2 - V_0^2}$$

and, according to formula (5)

$$2k^2 \mu = (V^2 - V_0^2)^{3/2} / X$$

Therefore,

$$r = \frac{\sqrt{V^2 - V_0^2}}{X}$$

For eccentricities which are not very nearly equal to 1, we had

$$X > \frac{3^{3/4}}{\sqrt{2}} \sqrt{e},$$

and it is certainly

$$r > \frac{3^{3/4}}{2} \sqrt{e} \sqrt{V^2 - V_0^2} \quad t > 1.05 \sqrt{V^2 - V_0^2} t \quad (10)$$

For  $V_0 = 0$

(10) is naturally changed into (9). For the hyperbola, however, it is possible to suggest a second relationship.

Since

$$\frac{2^2}{r} = \frac{V^2 - V_0^2}{V_0^2}$$

(5) can also be written

$$k^2 \mu = \left( \frac{a}{r} \right)^{3/2} V_0^2 X$$

and because  $k^2 \mu = e V_0^2$ , it follows that

$$r = \sqrt{\frac{e}{r}} \quad V_0 X = V t y,$$

where

$$y = \frac{e - \cos F}{\cos F} \cdot \frac{1}{\sin F - \log \tan (45^\circ + 1/2 F)}$$

NO. 1206, VOL. 47]

An easy calculation yields now

$$\frac{\partial y}{\partial t} = \frac{-1}{e \sin F - \cos F \log \tan (45^\circ + 1/2 F)} [(1 + e^2) \cos F - 2e + e \sin F \log \tan (45^\circ + 1/2 F)].$$

It is quite evident that the quantities in brackets always remain positive, for it is

$$\log \tan (45^\circ + 1/2 F) = 2 \tan \frac{1}{2} F + \frac{1}{3} \tan^3 \frac{1}{2} F + \dots > 2 \tan \frac{1}{2} F,$$

and in consequence of it the quantity in brackets  $> (e - 1)^2 \cos F$ . Thus,  $\frac{\partial y}{\partial F}$  is negative, and  $y$  decreases as  $F$  increases. From

this it follows that  $y > 1$ , and the relation  $r > V_0 t$  is the result.

If we apply this formula to Nova Aurigæ, we obtain for

$$\frac{V_0}{V} = 0.5 \sqrt{V^2 - V_0^2} = 108 \text{ miles, } V_0 = 60$$

0.6	96	72
0.7	86	84
0.8	72	96
0.9	—	108

In the vicinity of perihelion the velocity has been under every condition greater than 120 miles, and we shall therefore obtain values of  $r$  that are considerably too small, by supposing  $r > 85$  miles. One day before or after perihelion it is therefore certain that  $r > 7.3$  million miles.

It will therefore hardly be possible to assume that any noticeable influence of the supposed two bodies can have lasted longer than a few hours.

Since the above article was written Nova Aurigæ has by its reappearance attracted considerable attention, and especially by the observation as made by Prof. Barnard. With regard to this reappearance one must necessarily see an evident confirmation of the critical part of my article. Nor has my hypothesis been contradicted in any way, for it is evident in itself that the supposed formations of the nebulous or dusty matter are more copious in certain parts of space, and one may have different ideas of the distribution of density of these formations.

To the observation made by Prof. Barnard (*Astr. Nach.*, 3114) I wish to add the following remarks. I had formed an idea of the whole process which caused the outburst of the Nova, which idea is as perfectly represented in Prof. Barnard's drawing, kindly communicated to me by Prof. Kreutz, as I could expect. During the appearance of the Nova in the winter nothing similar was seen so far as I know. It does not follow from this, therefore, that it did not exist, and it would also have been possible to have expected information from the photographs as has often occurred before. I applied on this account to Dr. Wolf, in Heidelberg, and asked him whether he had photographs of the region of the Nova at that time, and whether, perhaps, any nebulous object was to be seen on them, but, unfortunately, Dr. Wolf did not possess such photographs. It remains doubtful, I am sorry to say, whether so delicate an object would have been visible on the plates. W. J. LOCKYER

#### HINTS FOR COLLECTORS OF MOLLUSKS.

AFTER the collector has brought home the spoils of his excursion there is still a good deal to be done before the wet and dirty shells, covered with parasitic growths or inhabited either by the original mollusk or some hermit crab, will be ready to be placed in the cabinet. Some of them, if living, may find a temporary place in an aquarium for the study of their habits, but, for the most part, the collector will wish to prepare his specimens either for anatomical use in the future or as dry specimens for his cabinet. The preparation of mollusks for anatomical purposes has been described in a special chapter of these instructions. For ordinary rough work nothing is better than clean 90 per cent. alcohol diluted with a proper proportion of water. If the specimens are large they should be first put into a jar kept for that special purpose, in which the alcohol is comparatively weak, having, say, 50 per cent. of water added to it. After the immersion of specimens in this jar for several days the fluids will have been extracted by the alcohol, and a specimen can then be removed, washed clean of mucus and dirt, which will almost always be found about the aperture of a spiral shell, and

<sup>1</sup> Reprinted from "Instructions for Collecting Mollusks, and other Useful Hints for the Conchologist," by William H. Dall; issued by the Smithsonian Institution as Part G of *Bulletin* of the U. S. National Museum, No. 39.

placed in its own proper jar of 90 per cent alcohol diluted in the proportion of 30 per cent with pure water. Specimens to be prepared for the cabinet require the removal of the soft parts if they are still present, the cleaning off of parasitic or incrusting growths, and, in the case of bivalves, securing the valves in a convenient position for the cabinet. The different classes of shells may be treated under several heads.

#### Land and Fresh Water Shells

Land and fresh water shells are much more easy to deal with than marine shells. In the case of spiral shells, such as *Livina*, *Planorbis*, *Paludina*, &c., the shell may first be washed clean of mud or coniferoid growth, which may be conveniently done with the assistance of an old tooth or nail brush. In the case of these forms the easiest way to remove the soft parts is to place the shell for twenty-four hours in weak alcohol, after which those parts can readily be removed, but in any case where the expense of alcohol is an object to be avoided, it will be sufficient to place them in a small tin kettle, or other receptacle suitable for the purpose, and cover them with cold water, which should then be slowly brought to the boiling point. As soon as it has reached the boiling point it may be removed from the fire. The shells should not be put into water already boiling, as it frequently cracks delicate shells, and the sudden change of temperature injures their polish and general appearance.

For removing the soft parts from spiral shells the collector will usually find a crooked pin sufficient. For this purpose one of those long steel pins used by ladies as hat pins is convenient. By heating the pointed end in the flame of a candle or alcohol lamp the temper can be taken out of the steel, so that it can be readily bent into any shape desired. The proper form for reaching the retracted parts in a spiral shell will of course be a spiral. With a small pair of pliers, different forms can be experimented with, and those which are most satisfactory decided upon. After the right form has been obtained, by heating the pin again and plunging it suddenly into cold water, the temper of the steel will be measurably restored and the instrument ready for use. Similar pins in their ordinary condition are convenient for cleaning out sand or parasites from the recesses of sculptured shells, and for other purposes. The attachment of a gastropod to its shell is at the central axis or pillar of the shell, usually from half a turn to a turn and a quarter behind the aperture. By applying the pressure of the extractor carefully in this vicinity the attachment will give way and the extractor may be withdrawn, bringing with it the soft portions of the animal. In large and heavy shells, in which the muscular attachments are strong and deep-seated, and it is desired to obtain a good hold of the animal in order to extract it from the shell, ordinary steel fish-hooks may be used. These may be softened by heat, straightened out, and twisted into a spiral of the proper form, and retempered. Then they can be securely fastened to small wooden handles by the shank of the hook. In this way the barb of the hook will assist in retaining the soft parts on the extractor when it is withdrawn from the shell. Several German firms advertise sets of implements for cleaning, cooking, and extracting the animals from shells of mollusks, but it would seem to the writer that any person of ordinary intelligence and some little mechanical ingenuity, such as all naturalists are expected to possess, should be able to provide himself with the necessary apparatus without purchasing expensive paraphernalia of this kind. Shells which have no operculum require merely to be cleaned after the animal has been removed, and in the case of land and fresh-water shells this is usually a very simple matter. Shells which possess an operculum should retain it in the cabinet, as it is often of great value in determining the relations of the species, since the operculum is a characteristic feature in the economy of the animal. It should be detached from the body of the animal after the latter has been extracted from the shell, carefully washed and cleaned, and if flat and horny may be dried between two pieces of blotting paper, under a weight. This will prevent it from becoming contorted in the process of drying. For removing the thick incrustation of lime and peroxide of iron which frequently forms upon fresh-water shells, a few tools resembling engraver's tools or the little chisels in use by dentists for excavating teeth are very convenient. A suitable tool, however, can easily be made by softening and grinding down an old file to a triangular point. A little experience will enable the collector to become expert in scaling off the objectionable matter without injury to the surface of the shell.

Wetland slugs should be preserved in alcohol, after being

sketched in the living state. Some of the older naturalists had a way of skinning slugs, inflating and drying the empty skins for preservation in their collections, much as entomologists sometimes treat caterpillars, but this ingenious device has nothing to recommend it to a scientific collector, even if he has the dexterity to practise it. The internal shell of such slugs as *Limax* may be represented in the collection if desired, but, in any case, specimens should be carefully preserved in spirits.

The bivalve shells, such as *Unio*, if taken alive, may be left in the sun for a short time, when they will usually open, and, the muscle connecting the two valves being cut, the valves may be cleaned. It is desirable for cabinet purposes to preserve the two valves in their natural position, attached to each other by the ligament which holds them together in life. This ligament dries to a very brittle, horny substance. Consequently the shells must be placed in position when fresh in order to make a success of the operation. After cleaning away the animal matter and thoroughly washing the interior of the shell, it is a good plan to note the locality with a soft lead-pencil upon the shell itself. Then bring the two valves together in their natural position and tie them in that position with a piece of tape or soft twine, which should be allowed to remain until the ligament is thoroughly dry. Specimens prepared in this way are more valuable for exchange and more attractive to the eye than those with which less care has been taken. It is always desirable, however, to have some specimens with separated valves of every bivalve species in the cabinet, in order that the characteristics of the interior may be easily examined.

Fresh-water bivalves are usually covered with a thin and highly polished, often very elegant, greenish or brownish epidermis. Sometimes the shell is so thin that, in drying, the contracting epidermis splits and cracks the shelly portion so that it becomes worthless for the cabinet. This often happens with marine mussels, but it is almost characteristic of the thin fresh-water *Unionidae*. Various methods have been adopted to prevent this unfortunate result. Some collectors have varnished their shells immediately after they were obtained. Others have used sweet oil or other oils in the hope of keeping the epidermis in a soft condition. These applications are all objectionable for one reason or another, as the first endeavour of the collector who desires to make a really scientific collection should be to keep his specimens as nearly as possible in a perfectly natural condition. The most satisfactory substance for application to the shells in question is probably ordinary vaseline, which should be applied in very small quantities, so that the specimen will have no greasy feeling and will absorb the vaseline sufficiently not to become sticky to the touch. Glycerine, which has been recommended by several collectors, like oil, leaves the surface sticky and offensive to the touch, besides rendering it liable to catch everything in the way of dust with which it may come in contact.

Very small gastropod shells need not have the soft parts removed. If they are put into a vial of alcohol for twenty-four hours, then taken out and allowed to dry, the soft parts will become desiccated without any offensive odour, and they may be placed in the cabinet without further preparation. It may be noted, however, that if the cabinet contains many such shells, care should be taken to guard against the access of mice and vermin, which are apt to attack them in the absence of something more attractive in the way of food. For those shells which possess an operculum, after the operculum has been dried and the shell cleaned and ready for the cabinet, it is customary to insert a little wad of raw cotton, rolled so as to fit the aperture snugly, the outer surface of it being touched with a drop of mucilage. The operculum can then be laid upon this in its natural position and the mucilage and cotton will retain it so without making it difficult to remove for an examination of the shell if desired at any time. For the preservation of eggs of mollusks when they have a horny or calcareous shell, small glass tubes securely corked are the best receptacles. Most of these eggs are so small that they may be preserved in a dry state or in alcohol without trouble, but the eggs of some of the tropical land snails are so large that it will be necessary to drill a small hole and extract the fluid contents as if they were bird's eggs in order to preserve them. Such eggs are the best preserved in alcohol.

#### Marine Shells.

The preparation of marine shells for the cabinet does not essentially differ from that required for land or fresh-water shells, except that in the marine shells the muscular system is

often much more strongly developed and the creatures themselves much larger than the fresh water forms, and the manipulation is therefore somewhat more difficult. The marine forms are also more apt to be incrustated with foreign bodies, bored by predatory sponges, like *Cliona*, or even by other mollusks, or perforated by certain annelids which have the power to dissolve the lime of which the shell is composed, and in this way secure a retreat for themselves.

Shells which do not contain the living animal are frequently occupied by hermit crabs or by tubicolous annelids. The latter fill up the larger part of the spire with consolidated sand or mud, in the centre of which they have their burrow. The hermit crabs do not add anything to the shells which they occupy, but, on the contrary, by their constant motion are apt to wear away the axis or pillar of the shell, so that often a specimen of this sort may be very fairly preserved and yet on the pillar show characters entirely different from those which one would discover in a specimen which had never been occupied by a crab. A shell which the crab has selected for its home is often taken possession of, as far as the outside is concerned, by a hydractinia, a sort of polype, which produces a horny or chitinous covering which is very difficult to remove from the shell to which it is attached. As the hydractinia grows it finally covers the whole shell, to some extent assumes its form, and then, if the creature has not attained its full growth, this is apt to take place around the edges of the aperture, which are continued by a sort of leathery prolongation which assumes in a rough way the form of a shell. The crab, when he grows too large for the shell in which he has ensconced himself, is usually obliged to abandon it and find a larger one, which is always a difficult and more or less dangerous operation, but if his shell is overgrown by the polype referred to, it often happens that the polype and the crab grow at about an equal rate, so that the latter finds himself protected and does not have to make a change. It is supposed that the polype profits to some extent by the microscopic animals attracted by the food or excrement of the crab, so that this joint housekeeping is mutually beneficial, and, for such cases, since the word *parasite* would not be strictly accurate, the word *commensal* has been adopted. These modified shells often assume very singular shapes. The polype is able in the course of time to entirely dissolve the original calcareous shell upon which its growth began, so that if the spire be cut through it would be found throughout of a horny or chitinous nature. Some of the older naturalists were deceived by forms of this sort and applied names to them, supposing that they were really molluscan shells of a very peculiar sort.

In removing the animal matter from the shell of large gastropods it will often require a good deal of time and care to get out all the animal matter from the spire, but it is well worth while to take the trouble, as the presence of such matter forms a constant attraction for museum pests of all descriptions. A medium-sized syringe is convenient for washing out the spire of such shells. The ordinary marine gastropods may be treated in a general way like the fresh-water gastropods. There are, however, abnormal forms, especially among tropical species, which require particular attention. Some species become affixed to corals and overgrown by them, retaining only a small aperture through which the sea water can reach the prisoner. Such specimens are best exhibited by retaining a part of the coral and cutting the rest away, showing at once the mode of occurrence and the form of the covered shell. Boreas are always more difficult to handle and prepare for the cabinet than other mollusks. They are usually more or less modified for their peculiar mode of life, and frequently rely upon their burrow as a protection, so that the shell is reduced, relatively to the animal, to a very small size. Most of these forms are best kept in alcohol. The hard parts may properly be represented in the cabinet by other specimens. Some of the bivalves, such as the American "soft clam," possess very long siphons, covered with a horny epidermis, and it becomes a question as to whether an attempt should be made to preserve this epidermis in the cabinet or not. The writer has seen very nicely prepared specimens in which the fleshy portions had all been taken out and replaced by cotton, so that the epidermis of the siphon retained its original position and form; but such specimens are always very delicate, easily broken, and liable to attack by insects, so that it would seem hardly worth while to go to the trouble, when specimens may be preserved complete in alcohol showing all the features referred to. Boring shell-

fish, like *Pholar*, frequently have accessory pieces, which are liable to be lost when the soft parts are removed unless care is taken to avoid it. Other bivalves have the internal ligament reinforced by a shelly plate, which is called the ossiculum. This is very easily detached and lost, and, being an object of great interest, special pains should be taken to preserve it, even if it should become detached.

### JAPANESE CAMPHOR

THE United States Consul at Osaka gives in a recent report the following particulars, reprinted from the November number of the *Board of Trade Journal*, respecting the Japanese camphor trade:—

The camphor tree, from which the resinous gum is distilled, is a species of the laurel, and is found in the provinces of Tosa, Hiuga, and Satsuma, in the south of Japan. Large groves of the trees are owned by the Japanese Government, the wood being very desirable for shipbuilding. The districts in which the camphor tree is found are mountainous and situated far from the sea. No reliable information can be obtained as to the cost of producing the gum before being transported in junks to Hio-go. The peasants who engage in distilling the roots and branches of the trees are said to be poor, and employ the rudest machinery.

The market value of crude camphor gum and of oil of camphor per picul (133½ lbs.) during the past year was as follows:—  
Drained, 38 25 dols.; wet, 37 00 dols.; old dry, 43 50 dols.; average, 36 50 dols.; camphor oil, 5 25 dols.

The highest and lowest prices during the same period were as follows:—Highest, 40 00 dols.; lowest, 33 00 dols.

Camphor gum is exported in tubs measuring about 6½ cubic feet, oil in kerosene tins and cases. The grades are from old dry down to new wet, and the various grades depend upon the quantity of adulteration. In oil there are two grades—white and brown.

Adulteration is practised for the most part by adding water and oil just as far as the buyer will tolerate. In some cases 20 lbs. of water will run out of a tub in twelve hours. The unadulterated article, known as the good old dry, can sometimes be bought. The only system of tests in determining value of the different qualities is by burning and by absolute spirit. The percentage of pure camphor which the crude yields when refined varies according to the quality of the crude. The average percentage of gum produced from the wood as compared with the original weight of the wood cannot be accurately ascertained here, the only foreigner known to have visited the camphor districts having declined to furnish any information on the subject.

The total exports of camphor from Hio-go during 1891 in cattles of 1½ lbs. each amounted to 3,850,400 cattles consigned to the following destinations: Europe (countries not specified), 1,777,300 cattles; London, 335,600 cattles; Germany, 209,200 cattles; United States, 1,277,000 cattles; China, 51,900 cattles; France, 199,400 cattles.

As regards the manufacture of camphor the following particulars are extracted from a report by the United States Consul at Nagasaki.

Camphor is found alike on high elevations and in the valleys and lowlands. It is a hardy, vigorous, long-lived tree, and flourishes in all situations.

Many of these trees attain an enormous size. There are a number in the vicinity of Nagasaki which measure 10 and 12 ft. in diameter. The ancient temple of Osiwa, at Nagasaki, is situated in a magnificent grove of many hundred grand old camphor trees, which are of great age and size, and are still beautiful and vigorous. It is stated that there are trees at other places in Kiu Shiu measuring as much as 20 ft. in diameter. The body or trunk of the tree usually runs up 20 and 30 ft. without limbs, then branching out in all directions, forming a well-proportioned, beautiful tree, ever green and very ornamental.

The leaf is small, elliptical in shape, slightly serrated, and of a vivid dark-green colour all the year round, except for a week or two in the early spring, when the young leaves are of a delicate, tender green. The seeds or berries grow in clusters and resemble black currants in size and appearance. The wood is used for many purposes, its fine grain rendering it especially valuable for cabinet-work, while it is used also for shipbuilding. The roots make excellent knees for ships.

In the manufacture of camphor the tree is necessarily destroyed, but, by a stringent law of the land, another is planted

in its stead. The simple method of manufacture employed by the natives is as follows:—

The tree is felled to the earth and cut into small pieces, or, more properly speaking, into chips.

A large metal pot is partially filled with water and placed over a slow fire. A wooden tub is fitted to the top of the pot, and the chips of camphor wood are placed in this. The bottom of the tub is perforated so as to permit the steam to pass up among the chips.

A steam-tight cover is fitted on the tub. From this tub a bamboo pipe leads to another tub, through which the enclosed steam, the generated camphor and oil flow. This second tub is connected in like manner with a third. The third tub is divided into two compartments, one above the other, the dividing floor being perforated with small holes, to allow the water and oil to pass to the lower compartment. The upper compartment is supplied with a layer of straw, which catches and holds the camphor in crystal in deposit as it passes to the cooling process. The camphor is then separated from the straw, packed in wooden tubs of 133½ lbs. each, and is ready for market.

After each boiling the water runs off through a faucet, leaving the oil, which is used by the natives for illuminating and other purposes.

### UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—Mr. W. Ridgeway, late Professor at Queen's College, Cork, has been elected to the Disney Professorship of Archaeology for the customary period of five years. Prof. Ridgeway's recent work on the origins of weights and measures have made him well known as a scientific archaeologist.

Mr. R. T. Glazebrook, F.R.S., Assistant Director of the Cavendish Laboratory, has been appointed a member of the Financial Board. Mr. Lewis, Professor of Mineralogy, and Dr. Gaskell, F.R.S., have been elected members of the General Board of Studies, and Mr. E. W. MacBride, Scholar of St. John's College, has been appointed Demonstrator in Animal Morphology, in the place of Mr. J. J. Lister, of the same College.

The Museums and Lecture Rooms Syndicate propose to introduce the electric light into the dissecting room of the Anatomy school, the lecture room, and histology class room of the Department of Physiology, and the Philosophical Library, at an expense not exceeding £100.

By the death, on November 30, of Dr. F. J. A. Hort, Lady Margaret Professor of Divinity, the University has lost not only a great theologian, but a distinguished student of science. Dr. Hort was second to Prof. Liveing in the Natural Sciences Tripos of 1851, the first ever held. He received the mark of distinction in Physiology and in Botany. In 1856, and again in 1871, he was an examiner for Honours in this Tripos. Throughout his life his interest in the scientific progress of the University was deep and hearty.

A Syndicate has been appointed to consider the whole question of the times of holding Tripos examinations, and the changes that would follow if these were altered. The disadvantages of the present system, by which much of the benefit of the Easter term and of the Long Vacation are lost to students and teachers alike, have of late been forcibly brought before the Senate. It is to be hoped that, by bringing about a rational "Easter" or otherwise, the Syndicate's efforts may lead to a reformation.

### SCIENTIFIC SERIALS.

*American Meteorological Journal*, November, 1892.—Wind measurement by H. W. Dines. The two instruments generally in use, viz. the Robinson cup anemometer and the pressure plate, are both more or less unsatisfactory in obtaining the extreme pressure. The wind never blows uniformly, whereas the instruments are calibrated on the supposition that it does so. And the method of exposure is often unsatisfactory; any obstacle to the free circulation of the wind either at the side or even behind or below the anemometer, vitiates the results. The usual factor for conversion of velocity to pressure in the equation  $P = kv^2$  is too high. The value 0.03 was given originally in a book on engineering, with a footnote stating that the experiments on

which it rested were doubtful, but it has since been copied without the note. Recent experiments show that 0.03 is probably more correct, but with such a varying element as the wind, any factor is of little use in deducing extreme pressures from velocity anemometers. Instruments of different sizes give different results, and those calibrated by indoor trials give more wind than those tested out of doors. In some respects it is more desirable to register the pressure than the velocity, but a pressure plate which is to register 30 lb. per square foot is hardly suitable to record so small a force as one ounce, so that on many days no sign of motion is given. The author concludes from many careful experiments that the tube form of anemometer is most likely to give satisfactory results, as, apart from electricity, it is the only kind in which the motion or pressure can be transmitted to a distance without loss by friction. In this instrument the registering apparatus is placed away from the part exposed to the wind.—The storms of India, by S. M. Ballou. In this article, which is a continuation of previous papers, the author treats of the storms which accompany the winter and summer rains.—The first aerial voyage across the English Channel, by R. de C. Ward. This voyage was successfully carried out by Dr. Jeffries and M. Blanchard on January 7, 1785. The balloon left Dover at 11 p.m. and descended a few minutes before 4 p.m., not far from Ardes.—On the production of rain, by Prof. C. Abbe. The author reviews the natural process of the formation of rain, viz. saturation by aqueous vapour, condensation into visible particles, and the agglomeration of these into drops large enough to be precipitated. The problem of artificial formation of rain will be partially solved if some method is invented to bring about a sudden formation of large drops out of the moist air that exists between the small particles of every cloud.

### SOCIETIES AND ACADEMIES

#### PARIS

Academy of Sciences, November 28.—M. d'Abbadie in the chair.—Note accompanying the presentation of a work on the new methods of the "Mécanique Céleste," by M. Poincaré.—On the existence of distinct nervous centres for the perception of the fundamental colours of the spectrum, by M. A. Chauveau. If one goes to sleep on a seat placed obliquely in front of a window which allows the light from white clouds to fall equally on both eyes, the coloured objects in the room appear illuminated by a bright green light during a very short interval when the eyelids are opened at the moment of awakening. The phenomenon is not observed except at the moment of awakening from a profound sleep. From this it is concluded that there are distinct perceptive centres for the green, and probably also for the violet and the red. Of these, the green centres are those which first regain their activity on awakening.—Note on the observatory of Mont Blanc, by M. J. Janssen.—On the laws of expansion of liquids, their comparison with the laws relating to gases, and the form of the isothermals of liquids and gases, by E. H. Amagat. The substances examined were water, ether, alcohol, carbon disulphide, hydrogen, nitrogen, air, oxygen, ethylene, and carbonic acid, the pressures ranging from 50 to 3000 atmospheres, and the temperatures from 0° to 200°. For both liquids and gases, the isothermals present a slight curvature turned towards the axis of abscissæ. The angular coefficient increases with the temperature. This effect is specially pronounced in the liquids, where it corresponds to a widening-out of the network, well exemplified in carbonic acid, in the part corresponding to the lower temperatures. This widening-out gradually disappears as the temperature rises, in the lighter gases, the variation with the temperature is very small.—Observations of Holmes's comet ("f" 1892), made at the Paris Observatory (west equatorial), by M. O. Callandreau.—On a remarkable solar protuberance observed at Rome on November 16, 1892, by M. P. Tacchini.—On universal invariants, by M. Rabat.—On straight-line congruences, by M. E. Cosserat.—On the passage of a wave through a focus, by M. P. Jouin. An apparatus for showing the complementary character of transmitted and reflected Newton's rings is mounted vertically, and illuminated by a small bright point placed at a distance of 1.20 m. along the axis of symmetry. On moving a microscope along the axis of reflection the rings first appear with a black centre, which changes into white at the first focus of reflection, and again into black at the second.—On the depression of the zero, observed in boiled thermometers, by M. L. C. Baudin. The secular

depression of the zero, brought into prominence by heating to 100°, may be greatly reduced by keeping the thermometers for several days immersed in a liquid boiling at 400° or 500°.—On the fusion of carbonate of lime, by M. A. Joannis.—Action of antimony on hydrochloric acid, by MM. A. Ditte and R. Metzner.—On the zincates of the alkaline earths, by M. G. Bertrand.—On anhydrous and crystallized fluorides of iron, by M. C. Poulenc.—Preparation of metallic chromium by electrolysis, by M. Em. Placet.—An aqueous solution of chrome alum, to which is added an alkaline sulphate and a small quantity of sulphuric or other acid, is electrolyzed. Pure chromium is deposited at the negative pole. It is very hard, and of a fine bluish-white colour. It resists atmospheric influences, and is not attacked by concentrated sulphuric acid, by nitric acid, or by concentrated potash solution. Articles made of brass, copper, or iron may be coated with chromium, thus giving them a metallic lustre resembling oxidized silver. Large quantities of the metal can be prepared without difficulty.—On the preparation of hydrobromic acid, by M. E. Léger.—Reply to M. Friedel's observations on the rotatory power of the diamine salt, by M. Alb. Colson.—Point of fusion of solvents as the inferior limit of solubilities, by M. A. Etard.—Action of the chlorides of dibasic acids on cyanacetic sodium ether, succinodicyanacetic ether, by M. Th. Muller.—On the functions of hydruilic acid, preparation of potassium hydruilate, by M. C. Matignon.—Researches on the colours of some insects, by M. A. B. Griffiths.—Microbicidal action of carbonic acid in milk, by M. Cl. Nourry and C. Michel.—On a nervous ganglion of the feet of *Phalangium opilio*, by M. Gaubert.—Myxosporidia of the bile duct of the Fishes, new species, by M. P. Thélohan.—On the modifications of absorption and transpiration which occur in plants under the influence of frost, by M. A. Prunet.—The rapid desiccation of the young shoots of frozen plants is due to the substitution of an intense evaporation for the normal function of transpiration, and to an almost complete suspension of absorptive function.—*Acids conium*, a new genus of Uredineæ, by M. Paul Vuillemin.—On the classification and the parallelisms of the miocene system, by M. Ch. Depéret.—On the existence of micro granulate and orthophyre in the primary formations of the French Alps, by M. P. Termier.—On the mineralogical modifications of the calcareous strata in the inferior Jurassic of Ariège due to lherzolite, and their bearing on the history of this eruptive rock, by M. A. Lacroix.—On the geographical distribution, the origin, and the age of the ophites and lherzolites of Ariège, by M. de Lacvivier.—Geological observations on the *Creux de Souci* (Puy-de-Dôme), by M. Paul Gautier.

## BERLIN

Physiological Society, October 28.—Prof. du Bois Reymond, President, in the chair.—Prof. Gad spoke on the respiratory centre on the basis of experiments made in his laboratory by Herr Marenescu. According to these, the centre for the co-ordination of the respiratory muscles lies in the *formatio reticularis grisea* and *alba* below the hypoglossal centre, on each side of the hypoglossal tract, whereas in the apex of the *calamus scriptorius* there is an inhibitory centre (*nœud vital*) whose stimulation may cause death. It further appeared from these experiments that the respiratory centre is not confined to a limited area, but is diffuse and quite distinct from Flourens's "*nœud vital*."

November 11.—Prof. du Bois Reymond, President, in the chair.—Dr. Ad. Loewy had investigated the influence on respiration of the upper tracts leading from the cerebrum to the respiratory centre, an influence which is specially marked after section of the vagi. He found that these tracts do not simply hand on to the centre impulses received from the periphery up the trigeminal nerve, but that they automatically maintain the rhythm of the centre after the vagi have ceased to function. Dr. René du Bois Reymond spoke on the sensation of warmth which ensues on immersing the hand in a vessel of carbon dioxide, Sulphurous acid, bromine vapour, nitrogen peroxide, ammonia and hydrochloric acid gas produce the same effect. The intensity of the sensation varies with the different gases. Thus carbon dioxide produces the same sensation as air warmed to 20°, while that of nitrogen peroxide is as of air at 30° and that of ammonia and hydrochloric acid gas as of air above 40°. The phenomena do not as yet admit of a physical explanation, but must be regarded rather as resulting from a chemical stimulation of the sensory nerves for heat perception. The President

exhibited a torpedo recently born in Berlin, in which he had detected an active electric organ immediately after birth, by means of a nerve muscle preparation and a galvanometer. This observation was first made in 1831 by Davy, but had not since then been repeated.

In the chapter on blood and lymph a fuller account of leucocytes with their varieties and functions, and especially of the proteid and other substances associated with them, would certainly have been desirable. It is of course easy, in reviewing so small a book, to find instances of curtailment and of omission, but the life history of the leucocytes is of supreme importance medically, that even the account of the derivatives of hæmoglobin might, for their sake, have been shortened.

The phenomena of muscular contraction are well described, and the account of muscle and nerve currents is especially clear and to the point.

In the chapter on the vascular mechanism two tracings of pressure in an artificial schema are taken from Prof. Foster's text-book. The tracings are accurately reproduced. In the description of these we are told that, after a high peripheral resistance is introduced into the circuit, "the pressure on the arterial side at first rises with every beat till it has attained a certain height, where it remains stationary, merely oscillating with every stroke of the pump. The venous manometer, on the other hand, shows no rise of pressure, and its oscillations become less and less, till they disappear and the flow becomes continuous." A glance at the tracing shows, however, that there is a rise of pressure on the venous side, and moreover a maintained rise. This is a very important point about the tracing. A student grasps readily the action of the arterial blood pressure in forcing the blood from the aorta to the capillaries, but he is at a loss to understand why it comes back again from the capillaries towards the heart. It cannot be too much insisted on that we have a pressure, a small and gradually falling pressure, in the veins, and that this is the important determining cause of the venous flow. The author, in this the proper place to bring this prominently forward, leaves it out entirely, though it is incidentally referred to later on, and leads the student to suppose that the presence of the valves in the veins and the aspiration of the thoracic movements, important though they may be, are the chief factors.

The subject of endocardial pressure and of the pulse is treated, clearly and concisely, in the light of Hurthle's important work. This is particularly welcome, as, if I am not mistaken, this is the first occasion that these researches have been brought before English readers.

In the discussion of the causation of the heart's beat it does not seem clear why "the beat always starts in the sinus" when we are told that the sinus contracts feebly and slowly. The fact that the sinus has a more rapid rhythm than the other chambers of the heart, and so initiates the whole cycle, is not distinctly brought out. The author follows Schmiedeberg's opinion in stating that muscarin acts by stimulating the nerve-endings of the vagus. This is by no means certain, and we should have welcomed some mention of Gaskell's opinion that its action is a direct one on the muscular tissue, and some of the reasons for taking that view. In the description of the vasomotor mechanisms I have found no adequate statement of the important part vaso-dilator nerves play in regulating the circulation in skeletal muscle.

In the account of the nervous mechanism of respiration, which is well up to date, in including some of the results of the work of Head, we should have expected also some statements of Marckwald's observations on the influence

of section of the medulla above the respiratory centre. No reference seems to be made of the influence of impulses reaching the respiratory from higher centres of the brain. It is also unfortunate that when the student turns, as directed, to Fig. 61 he finds that the tracing selected of the effect on the respiration of section of the vagi does not show the increase in amplitude as it does the decrease in rate, although he is told that both the changes are brought about. On page 266 there is an obvious misprint, the word "expiratory" should be "respiratory". On page 291 there is another misprint, " $B_2$ " in the equation should be, of course, " $Br$ ". A few lines further on there is, however, a serious error. We read, "From the amount of nitrogen given off the amount of urea present in the urine, may be calculated 35.5 c.c. of nitrogen correspond to one gram of urea." The theoretical amount calculated for one gramme of urea is 37.27 c.c. at standard temperature and pressure, while 35.5, or more exactly 35.4 c.c., is the amount which Hufner found was actually liberated not by one gramme, but by one decigramme of urea.

The chapters on the special senses and on the central nervous system are some of the best in the book. The methods of tracing fibres in the cord and brain are fully gone into, so also is localization of function, and indeed the account of the brain throughout is very clear and good.

At the end of the book is a short appendix, in which is given a description of apparatus purely physical in nature. Every teacher will agree with the author that it is not only desirable, but necessary, to put this in a manual of physiology. The ignorance of the construction and use of the simplest physical apparatus, which the average medical student carries with him into the physiological laboratory, is usually almost as perfect as it can be. Much of the time of a demonstrator of physiology has at first to be given to the teaching of some of the simplest physical methods.

L. E. S.

#### APPLIED MECHANICS.

*Elementary Manual on Applied Mechanics*. By Prof. Jamieson. (London: C. Griffin and Co., Limited, 1892.)

THIS is the latest addition to the series of books introduced by Prof. Jamieson during the last few years. Like his useful work on the Steam Engine, it is the outcome of the course of lectures which he delivers to his own students. It is replete with the many mechanical contrivances to be found in the workshop, one chapter being devoted to the consideration of the screw-cutting lathe alone.

The illustrations, with which the book abounds, and the necessary descriptions of the various machines considered, are all that one may wish for.

An excellent feature of the book will be found in the manner in which, after having enunciated a principle, the author has applied it to some well-chosen examples. In this direction he has proceeded to an extent which will be highly appreciated by the student. Further, he has availed himself of any opportunity to obtain results experimentally, and these form a very instructive series of examples for the young engineer.

A careful perusal will show that the author considers it desirable that all matters pertaining to units, definitions, symbols, &c., should be carefully attended to. But in his treatment of these he has not been entirely successful.

Take, for instance, his definition of the moment of a force on p 15 — "The moment of a force is equal to the force multiplied by the perpendicular distance from a point on its line of action." This is rather ambiguous, and we should prefer to see the words, *with respect to a point*, included in the definition.

In a footnote, p 214, objection is taken to  $f$  being used for acceleration, since it "naturally represents a force."

Then why use  $e$  for strain in the formula  $e = \frac{l}{L}$ , where  $e$  just as naturally represents an elongation, and strain is not an elongation, as the author clearly shows in another footnote on p 232?

Again, in a footnote on p 2 we have " $M = \frac{W}{g}$ , where  $M$  stands for the mass,  $W$  for the weight in pounds, and  $g$  for the acceleration of gravity."

Now on p 215 the reader is asked to accept as correct the formula for centrifugal force,  $P = \frac{Wv^2}{gr}$  lbs, but (continues the author) since  $M = \frac{W}{g}$ , then  $P = \frac{Mv^2}{r}$  poundals. Why should this substitution produce the change from pounds to poundals? We fail to see what is gained by having an ellipse for the figure representing motion in a circle.

There is a want of consistency when an acceleration is spoken of as " $a$  feet per sec in one second" in one place, and as " $a$  feet per sec." on p 219. On the same page, too,  $\frac{Wv^2}{2a}$  should evidently be read as  $\frac{Wv^2}{2g}$ .

The examples worked out in the chapter on bending moments will show the student how to apply the principle of moments to the case of a beam loaded in any given manner. This is preferable to merely using a set of formula, a system attended with most disastrous results.

At the end of each chapter will be found a good selection of examples on the matter considered therein. We are informed that another volume dealing with the more advanced portions of the subject is in the course of preparation.

G A B

#### OUR BOOK SHELF.

*Man and the Glacial Period* By G. Frederick Wright, D.D., LL.D., F.G.S.A. (London: Kegan Paul, Trench, Trübner and Co, 1892.)

THE title of this book raises expectations which the contents fail to satisfy. Out of 374 pages only sixty are devoted to the consideration of "the relics of man in the Glacial Period," and the treatment of the subject is, to say the least, uncritical. The reader does not learn from Prof. Wright that strong doubt has been expressed as to whether some of the "finds" of human relics in North America were really made in undisturbed glacial deposits, while his discussion of the European evidence is crude

and inadequate, not to say misleading. The author has apparently only a slight acquaintance with the literature of the subject, acquired chiefly from such recondite sources as Lyell's "Antiquity of Man," and treatises on general geology. Of the many interesting facts bearing on man's relation to the Ice Age which have been discovered since those works were published our author is apparently ignorant. Nor has "a summer spent in Europe" sufficed, as who could expect that it should, to make up for his other deficiencies. Fortunately, the major portion of his volume deals with the glacial phenomena of North America, for here he is on safer ground. We feel sure, however, that many of his statements and conclusions will receive scant support from geologists across the water. It would be interesting to know, for example, what evidence can be adduced to show that the southern part of the United States was submerged during the Glacial Period to the extent of 500 feet, so as to bring the waters of the Gulf of Mexico into Illinois and Indiana. Again, we were under the impression that the author's "Ohio Lake," which he supposes came into existence when the great ice-sheet advanced into that region, had been effectually disposed of by Mr Leverett and Prof. Chamberlin. Throughout the book the unity of the glacial period is confidently upheld, a view which Prof Wright is, of course, entitled to maintain, but he might have informed his readers that with few exceptions American geologists are quite of another opinion. He fails to understand the evidence adduced by Chamberlin and others in favour of the periodicity of glaciation, while so far as one can gather from his pages, he seems to know nothing of the facts bearing on this question which geologists in Europe have accumulated, especially during the past few years.

Altogether we much prefer the author's earlier work, "The Ice Age in North America," of which the present is more or less of an abstract. In the former the facts of American glacial geology were given in considerable detail, and the writer's crude speculations and hypotheses were less obtrusive. Should the present work come to a second edition we would advise Dr Wright to get some scientific friend to assist him in its revision. Loose unscientific phraseology and incorrect definitions are of not infrequent occurrence throughout the volume. Thus we read of "glacial ice," of "beautiful crystals of porphyry," &c, and are told that névé is the "motionless part" of a glacier, although a little further on we learn that it is from this "motionless" névé that "the glacier gets both its supply of ice and the impulse which gives it its first motion." Obviously Dr Wright is unacquainted with the observations of MM Pfaff, Kloebe, and Koch on the movement of névé, while he might increase his knowledge of glacier motion by studying what Messrs. McConnell and Kidd have to say upon that interesting subject.

*Beetles, Butterflies, Moths, and other Insects* By A W. Kapple and W. Egmont Kirby (London: Cassell and Co, 1892.)

THIS work is a slight sketch of the more prominent British insects, intended for youthful and very inexperienced entomologists. The first section is devoted to classification, the key to the orders of insects being a fairly workable one, though it takes no account of the very numerous exceptions. Then follows a section on structure, in which when describing the eye the authors ignore the latest experiments on the subject, proving that the compound eyes form but a single image of the object seen; they also treat the tongue or proboscis as if it were homologous throughout the orders, whilst in lepidoptera it is developed from entirely different organs from what it is in the others, except in the very lowest family; and again when describing the legs they fall into the almost incredible error of speaking of the first joint as the trochanter, saying it is joined to the thorax by a hinge-

plate, the coxa, the first joint being in fact the coxa and the trochanter, the short joint articulating it to the femur. Then follow short sections on the metamorphoses of insects and their habits and haunts, and longer sections on the collecting and preserving of perfect insects and larvæ, which are far more correct than the preceding ones, though very slight and quite insufficient for the initiation of a beginner. The main part of the book is devoted to short descriptions of the more prominent British insects under their various orders and families, and illustrated by twelve coloured plates, which are decidedly good for cheap chromographic work, this is by far the most useful portion of the book, and well-marked forms will easily be recognized from the figures and descriptions, even though many species are placed in their wrong families.

*Ostwald's Klassiker der Exakten Wissenschaften* Nos 31-37 (Leipzig Wilhelm Engelmann, 1892)

WE have already called attention to this admirable series of small volumes. It consists of scientific papers which may be said to have marked definite stages in the development of science. The only fault we have to find with the series, as we have already stated, is that only the German papers are given in the language in which they were originally written. All the others are translated. This is undoubtedly a mistake, for much may often depend on the precise words used by a great master of research. In other respects the series is excellent, and should be of genuine service to scientific students. The papers reproduced in the present set of volumes are Lambert's "Photometrie," three volumes (1760), photo-chemical researches, by R. Bunsen and H. E. Roscoe (1855-59), an attempt to find the definite and simple conditions in accordance with which the constituent parts of inorganic nature are connected with one another, by Jacob Berzelius (1811-12), on a general principle of the mathematical theory of induced electrical currents, by Franz Neumann (1847), observations on the moving power of fire and the machines fitted for the development of this force, by S. Carnot (1824).

## LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended or this for any other part of NATURE. No notice is taken of anonymous communications.]

### "Aminol, a True Disinfectant"

WILL you grant me space, in order to avoid misunderstanding, to make the following explanation?—

(1) I recently learned that certain samples marked "Aminol, a true disinfectant" have been sent to various gentlemen, accompanied by a leaflet, in which my name, without my authority, is associated with those samples. Allow me to inform your readers that those samples contain "aminol" in water in the strength of one in five thousand. Now, the experiments which I carried out with "aminol," as regards its disinfecting power of microbes, were made with a solution of the strength of one in six hundred, and the disinfecting power of this strength was the following: spores of *Anthrax bacilli* remained unaffected after eight hours' exposure, only after an exposure for twenty-four hours did the number of living spores decrease, but some escaped disinfection even after so long an exposure. *Anthrax bacilli*, *Staphylococcus aureus*, and others were destroyed, but only after a prolonged exposure.

(2) A substance is advertised and circulated under the name of "Periodate crystals," and is associated with my name without my authority. Until quite recently I have made no experiments with it. A few years ago I made a few experiments, merely of a tentative character, with a solution which was labelled "Periodate," but not with the substance advertised as

"Periodate crystals." With these latter I have recently made experiments, and I find that their solution in full strength has no disinfecting power on microbes, pathogenic and non-pathogenic, amongst which may be mentioned the bacillus and spores of anthrax, the bacillus of typhoid and of diphtheria, of cholera and of erysipelas, the *Bacillus prodigiosus*, the *Staphylococcus aureus*, and others. Likewise I find that injection of large quantities of the solution into guinea pigs already infected with anthrax or diphtheria, has no power whatever in arresting or altering the normal course of these diseases to their fatal issue.

L. KLEIN

### Tracery Imitation

I TOOK occasion some months ago to publish the result of observations on my child H's progressive attempts at drawing after outline "copies" set before her. Examination of the series of her drawings made almost daily during the period from her nineteenth to her twenty-seventh month showed in them no apparent form or shape. They are simply vigorous pencil markings, answering as well to one "copy" as to another—or to none. Quite suddenly, however, in her twenty-eighth month, she seemed to catch the idea of breaking the "copy" (man) up into parts, and succeeded in making head, body, arms, legs, &c., in sufficient degree of relative proportion to show that here was, in her case, the rise of what I called in the article cited, "tracery imitation" of a visual picture.

At that time I had no explanation to offer, but simply recorded the observation. I have now, however, reached a way of explaining the rise of this apparently abrupt connection between muscle sense and sight—an explanation suggested to me by a passage in Stricker's argument for the eye-movement theory of the visual apprehension of figure or outline.

Before a child begins to acquire "tracery imitation," his drawings have no shape, but they show uniformly certain systems of angles, curves, &c., due to the easiest and most natural movements of the arm. The eyes, however, have been in a measure already educated to recognize certain shapes or "copies." There are, therefore, in consciousness two series of associations—one of eye-movement sensations,  $a, a^1, a^2, a^3, a^4$ , &c., with a certain strength of revival, which we may call  $x$ ; the other, an associated series of arm-movement sensations,  $n, n^1, n^2, n^3, n^4$ , &c., representing a path of least resistance in arm movement. I let us call its strength or degree of tendency to progressive revival  $y$ .

Now, before the rise of "tracery imitation"  $y$  is greater than  $x$ , for the reason that the arm is restricted to a very few movements, and these are largely automatic. Once start one of these movements, and the tendency to carry it out is very strong. The tendency of the eye-movement series, on the contrary, to regular revival is slight, very few objects, copies, &c., being so clear and isolated as to give frequent unbroken reproductions. Consequently, the arm-movement series,  $n, n^1, n^2$ , &c., wins the day, and an abortive "drawing" is the result.

But the time comes soon when the reverse is true—when  $x$  is greater than  $y$ . The eye-movement series gets strengthened constantly by the repeated exploration of familiar figures, especially if, as in the case of my child, the eye be trained by having the same "copies" set from day to day. On the other hand, the arm and hand movement series gets constantly lesser and weaker, since the increasing mobility of the muscles, in the varied new activities of this period of infancy, is acquired at the direct expense of the early "cast iron" reactions which are largely organic. Both of these tendencies were very marked in H—the first, in the more pronounced recognition of the "copies" set before her; the second, in the less uncoth manner of holding her pencil, moving the fingers, disposing the arm, &c. Hence, it is simply a matter of education that  $x$  should soon overweigh  $y$ , and the elements of the eye series  $a, a^1, a^2, a^3$ , &c., should draw after them the arm series.

An association thus begins to be formed between the several members of the  $a$  series and certain correct elements of arm sensation; these latter go to form, under this leading, a new  $n$  series, which gradually becomes independent as an acquisition. That each new tracery combination is thus learned separately is seen in the fact that after H. learned to trace certain "copies" (man, bird), she was yet entirely unable to trace any others.

<sup>1</sup> *Science*, New York, January 8, 1892.

<sup>2</sup> "Du Langage et de la Musique" (French ed.), chap. xiii., see also his "Studien über die Association der Vorstellungen."

She was even unable to trace a circle, except as part of a man (the head)

In a paper presented at the London meeting of the International Congress for Experimental Psychology last August, I insisted that voluntary movements are possible in the child only after a great variety of motor "elements" have become available through great diffusion and mass in involuntary (imitative) reactions. The above phenomenon, thus explained, serves to illustrate the broader position

As there is no literature on this subject, the question of "tracery imitation" has not even been put before, to my knowledge, I should be glad to have opinions upon it. It is evident that if one hold the other theory of the visual apprehension of figure, *i.e.* that it is given by sight apart from sensations, of eye-movement, he could still hold the explanation which I have offered above, by substituting for the series of eye-movement sensations,  $a, a', a'', \&c$ , a series of visual sensations,  $v, v', v'', \&c$

J MARK BALDWIN

### Difficulties of Pliocene Geology

CONSIDERING the very great importance which the later tertiary beds must occupy in all speculations about the origin of man and the present geographical distribution of plants and animals, it is unfortunate that they should have attracted so little attention among English geologists.

The fact is perhaps not unnatural when we consider how very scantily they are represented in this country, the Norwich Crag being virtually the only bed where remains of pliocene land animals have occurred. The Norwich Crag is itself a very puzzling bed, where marine remains and land remains are found mixed together, the whole having been reassorted, and I do not know of a single pliocene land surface remaining intact in Britain. The so-called forest-bed can no longer be classed as pliocene, but is clearly of pleistocene age. A real mark of the true pliocene horizon in Europe is the occurrence of the mastodon and its associated fauna.

If we are to use the mastodon as a test we shall have to travel southward as far as Auvergne, if we are to find a pliocene land surface *in situ*. Unfortunately Auvergne is a very dislocated and broken country, and the sequence of the later deposits is very hard to make out, and I much question whether it be possible to find sections showing the true reading of the beds in question nearer than Florence.

I am writing in the hope that I may persuade Dr Forsyth Major, who knows the valley of the Arno so well, to communicate to NATURE some account of the results arrived at by the Italian geologists.

At present the question is one of great perplexity. Let me refer to two points. First, How comes it that in no part of the world, so far as I know, has a single fragment of an undoubted pliocene beast been found in a cave? The carnivora of pliocene times must have frequented caves just as much as the bears and hyenas of pleistocene times, yet how comes it that we can nowhere find any tertiary remains in any cavern? It will not do to appeal to denudation, for if there be deposits anywhere protected from denudation it is those in caves. Can it be that every mountain chain where limestone rocks occur is younger than pliocene times?

Again, we know that in America, both north and south, the mastodon survived to the end of the Pleistocene age, and lived alongside of the mammoth and the Columbian elephant. In Europe there is very great doubt whether the mastodon and any form of elephant were ever contemporaries. No doubt the teeth of the mastodon have been found with those of the elephant in the Crag, but the Crag have been so rearranged that it is impossible to draw any safe conclusions from them. It is at all events extraordinary that, according to the French geologists, the two beasts have never been found together in France. I believe the same conclusion has been arrived at by the Italian geologists, but upon this point there is some uncertainty, and it would be very interesting to have the opinion of so competent an authority as Dr Forsyth Major upon the point. It is one of importance, for upon it depends largely the question of whether there was a continuity in Europe between the pliocene and pleistocene land, or whether, as I am disposed to believe, there was a break between the two involving perhaps a violent revolution. There are other interesting

questions involved in the issue I have raised, upon which you may possibly permit me to write on another occasion. Meanwhile the burden of my present letter is to point out how little we really know about the pliocene land, and how useful it would be to know more.

HENRY H. HOWORTH

The Athenæum Club, December 5

### Meteors

A FINE meteoric shower was observed here on the night of November 23, from 7h 30m to 12h 30m, when the observations were interrupted by cloud. The meteors were evidently "Bielids," the radiant at 8h 30 being near a point, R A, 1h 20m, Dec, 40° 30'. The radiant, however, was not well defined, its area being at least 4" in diameter. For a single observer, in a position which commanded only about one-sixth of the visible hemisphere, the meteors numbered about six a minute, which would indicate at least seventy-five a minute for the entire sky, exhaustively observed.

At ten o'clock two observers, standing back to back in an open space, counted 104 meteors in five minutes, the position of the radiant being then, R A, 1h 30m, Dec, 41° 30'—very near Upsilon Andromedæ. At this time the radiant seemed to be rather more definite than earlier, and several nearly stationary meteors determined the place with reasonable precision.

An hour later a similar count by the same two observers gave 100 meteors in four minutes and a half, and the radiant was determined at R A, 1h 40m, Dec, 40°. The rate of frequency continued about the same until the sky clouded up an hour later, and must, I think, be estimated as high as from 80 to 100 a minute for the whole number that might have been seen by a sufficient corps of observers. This would foot up from 24,000 to 30,000 for the five hours.

I am not quite certain whether the apparent change in the position of the radiant is, or is not, real, but a motion very similar in amount and direction is given by Denza in his observations of the meteoric shower of 1885 (see NATURE, vol. xxxiii, page 151).

Comet "1" (Holmes's) was about 10° west and 4° south of the mean radiant at R A, 0h 40m, Dec, 36° 45'. It was barely visible to the naked eye.

Most of the meteors were very small, not exceeding the fifth magnitude, but a few, perhaps one in ten, were above the second, and in the course of the night four were seen which rivalled or surpassed Jupiter. The brighter ones left bluish trains, which remained visible for three or four seconds. The smaller ones often came in "flights" of three or four together, and fully half the paths were more or less curved and wavy from the resistance of the air.

It is worthy of notice that the heliocentric longitude of the earth at the time of the shower was about 62°, instead of 65° which was the longitude of the descending node of Biela's orbit at the last appearance of the comet in 1852, and was the longitude of the earth at the time of the showers of 1872 and 1885. The fact suggests the inquiry whether perturbations since 1885 will fairly account for such a recession of the node.

It is obvious also that if the meteoric swarms encountered by the earth in 1872 and 1885 were really moving in the orbit of Biela's comet (which at its last appearance had a period of 6.6 years), then the swarm encountered the other night, just seven years later, must have been an entirely different one—unless indeed the perturbations since 1885 can account for a retardation of nearly five months.

Last night was for the most part overcast, but a watch of fifteen minutes through occasional openings in the clouds showed only one or two possible Bielids. Evidently the shower was not continuing with any intensity.

C A YOUNG

Princeton, N.J., U S, November 25

### Comparative Sunshine.

AFTER explaining that by "sunshine" I intend that which would fall upon the earth if there were no atmospheric obstruction, one must first notice the very elementary truth that the amount of such sunshine at any assumed time and place is in proportion to the altitude of the sun at noon, and also the

<sup>1</sup> An abstract of the paper is to be found in *SCIENCE*, November 18, 1892, and also in the *Proceedings of the Congress*.

length of the day Except at the time of the equinox, the gradual lengthening or shortening of the day, as the solstice is approached, most materially affects, especially in the higher latitudes, the total amount of sunshine received in twenty four hours.

But are there any convenient and readily accessible tables—as there easily might be—which would at a glance show numerically the comparative amounts of sunshine at certain selected times and places? I would wish to see such tables, say, for every tenth day, for the three months from an equinox to a solstice, for about every third degree of latitude in each hemisphere. I see not how, without this, either the causes or the effects of meteorological changes in different regions at different seasons can be justly estimated. I would propose to express the amount of sunshine during twelve hours at the equator at the equinox by, say, 100, the figures rising above this, or falling below it. Thus there would be more than 100 given for the latitude of the Tropic of Cancer at the summer solstice, with a vertical sun and more than twenty four hours' sunshine, with 100 for a latitude still further north.

REGINALD COURTENAY

The Imperial Hotel, Sliema, Malta, November 14

### Quaternions

BY the kindness of the author I have just received a copy of Mr Heaviside's paper "On the Forces, Stresses, and Fluxes of Energy in the Electromagnetic Field" (*Phil Trans*, 1892, p 423), in which he reopens a question debated in your columns some time ago—the question of Quaternions *versus* other methods of vector analysis for the use of physicists.

At present the matter stands thus—There are two widely known systems of vector analysis before the public—Quaternions and the *Ausdehnungslehre*—and quite a multitude of less known ones, of which Prof. Gibbs seems to be one of the least open to objection, and of which, in my opinion, Mr Heaviside's is by no means so. It would take too long, however, to justify this opinion, but I wish to make an appeal to Mr Heaviside and Prof Gibbs on grounds independent of the merits or demerits of their particular systems.

Of the *Ausdehnungslehre* I do not feel competent to speak. As to Quaternions, there are undoubtedly some inconveniences in physical applications, and I am quite willing to concede that a grave one is the very frequent use of the letters S and V (Mr. Heaviside uses the latter). I do not regard the sign of the scalar product which vexes the soul of Mr Heaviside as of any consequence. But while thus admitting that a better system than Quaternions is conceivable, I think I can show, that the position of the dissenters is little short of suicidal.

The band of physicists who use and urge the use on others of vector analysis is woefully small. Let me put a question to two of the justly best known of that band, Prof Gibbs and Mr Heaviside. What is the *first* duty of the physical vector analyst *qua* physical vector analyst? I think I may anticipate that the answer will be—to convince the world of mathematical physicists that vector analysis must be unshelved and set to work. The next question that arises is one of tactics. What should be the plan of campaign to bring this desirable result about? Here I am afraid we cannot hope for unanimity even among the members of the small band, and this is to be most grievously deplored. But surely every sane man will agree that what most certainly the analysts should not do is to present their arguments to those they would convince in a dozen different mathematical languages, each of which is puzzling enough to those learned in allied languages. Grant this, and it follows that Quaternions and the *Ausdehnungslehre* should be left in sole possession of the field. The day for Prof. Gibbs's improvements is not yet. Prof Gibbs and Mr Heaviside have not yet convinced the rest of the small band—not to say each other—of the merits of their algorithms. Let me implore them to sink the individual in the common cause, and content themselves with the faith that posterity will do them justice.

Apart from the question of notation there seem to be two schools of opinion as to the proper conduct of the campaign. To vary the metaphor, Maxwell, Clifford, Gibbs, Fitzgerald, Heaviside prescribe a course of spoon-feeding the physical public. Hamilton and Tait recommend and provide strong meat. I do not think that harm, but rather good, will come from this double treatment, as one course will suit some patients and the other others. But let the spoon feeders provide spoon-

ment of the same *kind* as the other physicians. Is not Maxwell, Clifford, and Fitzgerald's food as digestible as Prof. Gibbs's and Mr Heaviside's?

ALEX. MCAULAY

Ormond College, Melbourne, October 31

### Animals' Rights

MR SALT disputes the justice of the statement that he has given two contradictory definitions of animals' rights, inasmuch as, according to him, that which he has set forth on p 28 is but a repetition and amplification of the one to be found on p 9.

By the definition on p 9 animals' rights are said to consist in a "due measure" of the restricted freedom which constitutes the right of man, *i.e.* (as Mr Salt notes) the freedom "to do that which he wills, provided he infringe not the equal liberty of any other man"—"a restricted freedom" which guarantees to the harmless individual *the security of his life and liberty*.

But on p 28 the rights of animals (which were said before to consist in a "due measure" of that just quoted) being here stated to be "subject to the limitations imposed by the permanent needs and interests of the community," are found to be burdened with so serious a qualification that *security for the life and liberty of the harmless individual is by it completely destroyed*.

A European might settle with confidence in an unknown island, on the assurance that he would be allowed a measure of the general right of the natives to the freedom to do that which they would, provided they infringed not the equal rights of any other, but were he afterwards to discover that the "measure" of this right which was considered to be the "due" of a foreigner was in reality limited "by the needs and interests of the community," and that, a community where the custom of enslaving and eating strangers had existed from time immemorial, we venture to assert that his departure from the island would be effected with as little delay as possible. We should much regret misrepresenting Mr Salt's statements, but the assertion that the second definition of rights is but a repetition and amplification of the first is manifestly untenable, and if, by "*due measure*" for animals of the rights of man, Mr Salt would have us understand that he meant—only such a measure as is consistent with the nullification of the most fundamental privileges secured by them, he must have been discussing the subject in a vein of sarcasm which we are bound to confess we had quite failed to appreciate.

THE REVIEWER

### The Height and Spectrum of Auroras

THERE was a magnificent aurora on the evening of the 4th, part of which, from 10h 46m to 48m. or 49m, was an intense red. I noted the positions of some of the features at the exact half hours and also at some other times, for comparison with any observations that may have been made in other places, for ascertaining the height of the phenomenon, and I hope some such observations have been made of the recent display, and will be made of further ones in the future, for Dr Veeder, of Lyons (New York), has kindly consented to calculate the heights from the observations.

I am surprised that none of our persevering photographers have as yet obtained a good photograph of the auroral spectrum. I do not think it would be more difficult than the stellar photographs that have been taken, seeing that the exposure might go on for hours. It would be desirable to have it done with a camera that could be pointed in any direction at will, so that wherever the observer saw a bright portion of the aurora he could direct the instrument to it.

T. W. BACKHOUSE.

Sunderland, December 6.

### The Teaching of Botany

THERE appeared in NATURE (vol. xxxi. p. 229) a paper entitled "Experiments suitable for illustrating Elementary Instruction in Chemistry," by Sir H. E. Roscoe and W. J. Russell. I have long felt the want of a similar series of experiments in physiological botany. There is not much difficulty in teaching the morphological side of the subject, but it is not easy for the ordinary high-school teacher to devise and carry out a suitable series of experiments for demonstrating the more important aspects of physiological botany. If some master in the

subject would do for botany what Sir H. E. Roscoe has done for chemistry he would confer a great boon on teachers and young students

### Egyptian Figs.

MY attention has been called to a very obvious slip of the pen in my note on Egyptian Figs, in that I have written "Pliny" instead of "Theophrastus". The former, as all know, was a *Latin* author, but he simply copies from the latter. Having both authors before me at the time, I accidentally put one name for the others. The refs. are as follows—Theoph. iv 2, Dioscor. i 1, Plin. xlii 7.

GEORGE HENSLOW

### A Palæozoic Ice-Age

I CANNOT understand how, when writing on this subject (*ante*, p. 101), I overlooked the circumstance that the ancient boulder-beds of Australia, India, and South Africa received full notice in Prof. J. Prestwich's "Geology," vol. ii pp. 143, 146.

December 9

W. T. BLANFORD

### SCHEELÉ

DURING this month Sweden commemorates the one hundred and fiftieth anniversary of the birth of one who has conferred an imperishable lustre on her annals. Carl Wilhelm Scheele—although a German by nationality, for he was born at Stralsund, the capital of Pomerania—spent practically the whole of his short life in Sweden, and is usually regarded as a Swede. The son of a tradesman, Joachim Christian Scheele, and the seventh child of a family of eleven, Scheele, as a boy, gave little promise of the genius and power which astonished the scientific world towards the close of the last century. It is perhaps indicative of a certain mental imperfection that he should have been wholly incapable of learning a foreign language, although he lived in Sweden during more than half his life his knowledge of Swedish was so imperfect that his memoirs, addressed to the Academies of Stockholm and Upsala, were invariably written by him in German and had to be translated by others before publication. By what influences he was led to the study of chemistry is unknown. There was nothing apparently in his home life, or in the mode or circumstances of his education to direct his inclination towards science. As a boy he began the study of pharmacy, and at his own wish was apprenticed to an apothecary at Göteborg named Bauch, with whom he remained eight years. Here he had access to the standard treatises on chemistry of that time, and he devoted all his leisure, often working far into the night, to the study of the works of Neumann, Lemery, Kunkel, and Stahl. Kunkel's *Laboratorium* was, indeed, his chief instructor in practical chemistry, and it was by diligently repeating, in the first instance, the experiments contained in that book that he acquired that extraordinary manipulative skill and analytical dexterity on which his success as an investigator ultimately rested.

When twenty-three years of age Scheele removed to Malmö, and some years afterwards to Stockholm, where he superintended the shop of an apothecary named Scharenberg. It was about this time that his career as a discoverer began, by the isolation of tartaric acid from cream of tartar. He ascertained many of the characteristic properties of this acid and prepared and examined a number of tartrates. These early efforts met, however, with a somewhat untoward reception. It seems that Scheele drew up an account of his observations and forwarded it to Bergman, who then filled the chair of chemistry in the University of Upsala as the successor of Wallerius. Bergman failed to appreciate the significance of the work of the young and unknown apothecary and by

some mischance the manuscript was lost. The importance of the discovery was, however, recognized by Retzius, who induced Scheele to write a second account of his work and to submit it to the Academy of Sciences at Stockholm, by whom it was eventually printed. In 1771 Scheele published his memorable essay, "On Fluor Mineral and its Acid," in which he first demonstrated the true composition of fluor-spar, showing that it "consists principally of calcareous earth saturated with a peculiar acid," named by him "fluor-acid." Although he found that the "fluor-acid" (hydrofluoric acid) dissolved "siliceous earth" he failed to recognize the change thereby produced in the "fluor-acid" and was thus led to an erroneous conception of its real nature. He was in fact led astray by the circumstance that his experiments were for the most part made in glass vessels, and hence the fluor-acid was contaminated with more or less silica and hydrofluosilicic acid. The origin of the silica in the acid prepared by Scheele was first clearly indicated independently by Wiegand and Meyer. In 1773 Scheele went to Upsala as pharmaceutical assistant to Mr. Lökk, in whose shop he chanced to meet the chemist Gahn. Lökk and Gahn were speculating on the cause of the different mode of action of distilled vinegar on nitre before and after fusion. This was explained by the young assistant, who pointed out the nature of the change effected on nitre by fusion, and the fact that it is converted into a salt (potassium nitrite) from which a peculiar acid, different from true "spirit of nitre," can be obtained by treatment with distilled vinegar. Gahn, struck with the sagacity of the young pharmacist, offered to introduce him to Bergman. The invitation was at first declined, Scheele had not forgotten the unfortunate incident of the tartaric acid memoir. Eventually he allowed himself to be convinced that Bergman's action was due more to inadventure than to indifference, and the acquaintance which followed rapidly ripened into a strong friendship. In 1774 Scheele, at the suggestion of Bergman, published his well-known memoir "On Manganese, Manganesium, or Magnesia Vitriarum." This essay, although marred and in part obscured by the phlogistic conceptions of the period, will for ever remain one of the classics of chemistry. In it Scheele not only established the nature of "pyrolusite" or "wad," but, in studying the action of acids upon the mineral, he was led to the discovery of baryta and of chlorine, the properties of which he minutely describes. In 1775 appeared his memoir on arsenic acid which he prepared in several ways; he discovered many of the more striking properties of this body and obtained a number of its salts. In the course of the investigation he discovered arseniureted hydrogen, and the well-known pigment Scheele's Green. In the same year he published his essay on benzoic acid, the "flowers of benzoil" of the apothecary. After a stay of two years in Upsala Scheele was appointed by the Medical College *provisor* of the pharmacy at Köping, a small town on the north shore of Lake Mälär. Instead of the prosperous business he had been led to expect he found nothing but discomfort and disorder, and the remainder of his life was spent in a constant struggle with privation and debt, relieved at length, to some extent, by a grant, at Bergman's instigation, from the Stockholm Academy. Of this money Scheele set aside one-sixth for his personal necessities, and devoted the remainder to his researches. In 1777 he took over the business of the pharmacy from the widow of the former proprietor, but it was only by unremitting industry that he was able to discharge the obligation he thereby incurred. Not a year passed, however, without Scheele publishing two or three memoirs, every one of which contained a discovery calculated to enhance his reputation as the greatest experimenter of his time. This untiring devotion to science at length began to tell upon a frame constitutionally weak and doubtless further enfeebled by privation, and by the worry

of debt and difficulties. He struggled on, however, a martyr to rheumatism and suffering from a complication of internal disorders until he was struck down in the spring of 1786. Some time before his fatal illness he had formed the resolution of marrying the widow of his predecessor so soon as his circumstances should permit. On his death-bed he carried out this project, bequeathing to his wife such property as he had been able to acquire. Two days afterwards (May 21, 1786) he died at the age of forty-four.

The eleven years during which Scheele lived at Koping were fruitful in investigations of the highest importance in every department of chemistry. In that time he discovered molybdic, tungstic, and arsenic acids among the inorganic acids, and lactic, gallic, oxalic, citric, malic, mucic, and uric among the organic acids. He also discovered glycerin, determined the nature of Prussian blue, and prepared hydrocyanic acid. He demonstrated that plumbago is nothing but carbon associated with more or less iron, and that the black powder left on the solution of cast-iron in mineral acids is essentially the same substance. He determined the chemical nature of sulphuretted hydrogen, discovered arseniuretted hydrogen, and invented new processes for preparing ether, powder of algaroth, calomel, and *magnesia alba*. He made numerous analyses of air by absorbing the oxygen with a mixture of iron filings and sulphur. He concluded that "our atmosphere contains always, though with some little difference, the same quantity of pure or fire air [oxygen] viz.  $\frac{1}{4}$  which is a very remarkable fact, and to assign the cause of it seems difficult, as a quantity of pure air [oxygen] in supporting fire, daily enters into a new union, and a considerable quantity of it is likewise corrupted or changed into aerial acid (carbon dioxide) as well by plants as by respiration, another fresh proof of the great care of our Creator for all that lives."

Scheele's greatest work, however, is unquestionably his treatise on "Air and Fire," which appeared in 1777 with a preface by Bergman, who, according to Thomson, superintended its publication. This elaborate essay shows Scheele at his best and at his worst, it testifies to his genius as an experimentalist and to his weakness as a theorist. No one can read this, or indeed any other of Scheele's memoirs, without being impressed by his extraordinary insight, which at times amounted almost to divination, and by the way in which he instinctively seizes on what is essential and steers his way among the rocks and shoals of contradictory or conflicting observations. No man was ever more staunchly loyal to the facts of his experiments, however strongly these might tell against an antecedent or congenial hypothesis. Had Scheele possessed that sense of quantitative accuracy which was the special characteristic of his contemporary Cavendish, his work on "Air and Fire" would inevitably have effected the overthrow of phlogistonism long before the advent of Lavoisier. His memoir is essentially an essay on oxygen, of which he was an independent discoverer, in its relations to life and combustion. It is perhaps idle to speculate on the causes which prevented his clear recognition of the full truth. It may have been that he was essentially a *preparateur* like Priestley, and that quantitative chemistry had few attractions for him, it is far more probable that the character of his work was determined by the circumstances of his position, by his poverty, his lack of apparatus, and his want of assistance. As it is, it remains one of the most remarkable circumstances in the history of human knowledge that a man working under such adverse conditions in a small village on the shore of a Scandinavian lake should have been able to change the entire aspect of a science.

It was stated by Crell, the editor of the well-known *Neue Entdeckungen und Annalen*, in which many of Scheele's papers first appeared, that the great Swedish

chemist was invited to this country with the offer of an easier and more lucrative position than that which he had at Koping, but that his partiality for Sweden and his love of quiet and retirement delayed his acceptance of the offer until a change in the English ministry put a stop to the negotiations. Thomson, the author of the "History of Chemistry" in mentioning this circumstance, expresses his doubts as to its truth, and states that he made enquiries of Sir Joseph Banks, Cavendish, and Kirwan, but none of them had ever heard of such negotiation. Indeed the circumstance is intrinsically improbable. "I am utterly at a loss," says Thomson, "to conceive what one individual in any of the ministries of George III was either acquainted with the science of chemistry or at all interested in its progress." What minister in Great Britain ever attempted to cherish the sciences, or to reward those who cultivate them with success? If any such project ever existed, it must have been an idea which struck some man of science that such a proposal to a man of Scheele's eminence would redound to the credit of the country. But that such a project should have been broached by a British ministry, or by any man of great political influence, is an opinion that no person would adopt who has paid any attention to the history of Great Britain since the Revolution to the present time."

T. E. THORPE

#### WERNER VON SIEMENS.

ERNST WERNER SIEMENS was the eldest son of Christian Ferdinand Siemens and Eleonore Deichmann, he was born in 1816 at Lenthe in Hanover, where his father was engaged in the business of agriculture and forestry.

From his very childhood the subject of this memoir learnt the lessons of self control and responsibility, for owing to his mother's delicate health and his father's occupations, the care of his younger brothers and sisters devolved on himself and his sister Mathilde. In these younger days he also learnt tact, and his father taught him that difficulties had to be faced and overcome, and that duties must never be avoided.

In 1823, a few months after the birth of his brother William (whose lamented death occurred here nine years ago), the family removed to Menzendorf near Lubeck, in the Grand Duchy of Mecklenburg. In the Gymnasium of Lubeck Werner was educated up to his eighteenth year, when, by the advice of his father—who with rare prescience saw in Prussia the nucleus of German Unity and Empire—he went to Magdeburg to volunteer for service in the Prussian Army. For three years he studied in the Military School of Berlin, and in 1838 received his commission as a lieutenant in the artillery, and returned to Magdeburg, he was soon transferred to the Technical Division of the Artillery at Spandau, and afterwards to Berlin.

In July, 1839, his mother died, and six months afterwards his father, and then, at only twenty-three years of age, he became the veritable guardian of his younger brothers and sisters.

In 1842 he took out a patent in Prussia for electroplating and gilding, and having established a factory in Berlin for putting his invention into practice, he urged his brother William to devote his attention to the subject. This the younger brother did, and the story of his enterprise and success in this country then and ever since has been told by Dr William Pole in his most interesting biography of him, to this volume and to the works of Dr Werner von Siemens, the first volume of a translation of which has recently been published by Mr Murray, we are indebted for much of the information contained in this short notice.

In 1844 the young artillery officer was appointed to the important post of Superintendent of the Artillery workshops, and in 1847 he became a member of the commission then instituted for introducing the electric telegraph into Prussia. Next year his military duties called him to Kiel, where in conjunction with his brother-in-law, Prof. Himly, he protected that port against the attack of the Danish fleet, by means of submerged mines connected with the shore by cables, at once the precursor of the submarine cable and the torpedo. In the summer of 1848, as commandant of Friederichsort, he built the fortifications for the protection of the harbour of Eckenförde, which afterwards became so celebrated. In the same year he was recalled to Berlin in order to erect a line of telegraph from Berlin to Frankfort-on-the-Maine, the first electric line laid in Germany, and with this his official military career terminated, and he devoted his attention altogether to those scientific discoveries and

inventions which have made the name of Siemens a household word in every region of the globe.

In 1874 Dr. Werner Siemens was elected a member of the Royal Academy of Sciences of Berlin, and the speech he made upon that occasion enables one to understand and appreciate his connexion with physical science. He was professionally connected with the application of science, which unfortunately left him but little leisure for those purely scientific investigations to which he always felt specially attracted. He says, to quote his own words in the speech just referred to, "My problems were generally prescribed by the demands of my profession, because the filling up of scientific voids which I met with presented itself as a technical necessity. I will only here mention cursorily my method of measuring high velocities by means of electric sparks, the discovery of the electrostatic charge of telegraph conductors and its laws, the deduction of methods and formulae for testing underground and submarine cables, as well as for determining the position of faults occurring in their insulation,

my experimental observations on electrostatic induction, and the retardation of the electric current thereby, the conception and realization of a reproducible basis of measurement for electrical resistance, the proof of the heating of the dielectric of a condenser by sudden discharge, the discovery and explanation of the dynamo electric machine. I think I may claim that many of my technical contributions are not without scientific value, among which I may mention the differential regulator, the manufacture of insulated conductors by pressing gutta-percha around them, telegraphic duplex, diplex, induction and automatic recording instruments, the ozone apparatus, and measuring instruments of different kinds. I had the honour of seeing these recognized by receiving from the Berlin University the distinction of Doctor of Philosophy, *honoris causa*."

The reply to this speech was made on behalf of the Berlin Academy by Prof. du Bois Reymond, the Secretary of the Physical and Mathematical Section, and some of the words he then spoke will show how Germany appreciated one of her ablest sons, one whom we also may claim, for when Werner Siemens was born, the King of England was Elector of Hanover. "By appropriating such a scientific form as yours, my dear Siemens, no Academy need be untrue to the laws of its foundation. Yours is the talent of mechanical discovery, which primitive people not improperly described as divine, and the cultivation of which constitutes the ascendancy of modern culture. Without having yourself worked with your hands in practical mechanics, you have reached the highest point in that art as creating and organizing head. With clear view and daring mind you soon grasped the great practical problems of electric telegraphy, and thus secured to Germany an advantage which Gauss, Wilhelm Weber, and Steinheil could not have procured for it. Your labours were for electricity what Fraunhofer's were for light, and you are the James Watt of electro-magnetism. Now you rule over a world which you created. Your telegraph lines surround the globe. Your cable ships navigate the ocean. Under the tents of nomads using bows and arrows, through whose hunting grounds your messages pass, your name is mentioned with superstitious awe."

This poetical description is fully justified by the great undertakings that have been carried out by the Siemens firm. The Indo-European telegraph, 2750 miles in length, passes across Europe, through a part of Russia to Tabreez and Teheran in Persia, and thence to India. But for the international character of the firm this work could probably never have been accomplished. But with Mr. Carl Siemens in St. Petersburg, Dr. Werner in Berlin, and Mr. William in London, to carry out the necessary negotiations, the tender was accepted in June, 1869, and the work was completed in December of the same year. Since then eighteen cables of a total length exceeding 21,000 miles have been constructed at their Woolwich works and laid in the Atlantic by the *Faraday*, by the firm of Messrs Siemens Brothers and Co., Limited, of which firm Dr. Werner von Siemens was Chairman and Mr. Alexander Siemens is the Director in London.

In a single line of the speech just alluded to Dr. Werner refers to the dynamo machine. On this machine the whole supply of electricity for lighting, transmission of power, and other large purposes is dependent; and it is interesting in this connexion to note that the only rival to the electric light for large effects is the regenerative gas lamp invented by Dr. Werner's youngest brother, Mr. Frederick Siemens, the inventor, with Sir William Siemens, of the regenerative gas furnace.

Dr. von Siemens was a Knight of the Prussian order *pour le mérite*, an honour conferred only on those who have been distinguished for their services to science and industry. The honorary degree conferred upon him by the University of Berlin, and his membership of the

Royal Academy of Sciences of Berlin, have already been referred to. Dr von Siemens was a member of many learned societies, and only in the spring of this year he was elected one of the sixteen honorary members of the Institution of Civil Engineers. The late Emperor Frederick III of Germany conferred upon him the patent of nobility in 1888, and the present Emperor has expressed his sympathy with his sorrowing widow and family.

Dr. Siemens was unfortunately one of those attacked during the influenza epidemic, and although he recovered from it, it left him weak, and he has since been ailing more than once. A work on which he has been spending his spare moments was an autobiography, giving reminiscences of himself and of the firm of Siemens and Halske. This was published in Berlin a fortnight ago. On Tuesday, the 6th inst., Dr. Werner breathed his last at half-past six in the evening, just within a week of completing his seventy-sixth year. It may truly be said of him that although he has passed from us, his life's labours will ever endure, having left an indelible mark on the world's progress.

The funeral took place on Saturday. The London, Belfort, Vienna, and St. Petersburg factories of the firm of which the deceased was a member, sent officials and workmen; the many thousands following the hearse, and the respectful attitude of the bystanders in the streets through which the funeral procession passed testifying to the regard in which he was held. The Emperor William was represented by Prince Leopold, the Empress Frederick by Count Seckendorff, and the German Empire by Chancellor Caprivi. Science and art and industry, the City of Berlin and the town of Charlottenburg were represented by deputies and deputations, all combining to do honour to one esteemed of all. E F B

### NOTES

WE are glad to announce that Sir Archibald Geikie has undertaken to write the Life of Sir Andrew C. Ramsay, his predecessor in the Geological Survey. Sir Andrew Ramsay spent nearly the whole of his scientific career in the service, so that the record of his life and the story of the progress of the Survey are closely bound together. This is the third member of the staff of the Survey whose memoirs Sir Archibald Geikie will have written, the two others being Edward Forbes (whose Life he wrote in conjunction with the late Prof. George Wilson) and Sir Roderick Murchison. Sir Archibald joined the staff under Ramsay, and grew into the closest relations of friendship with him.

WE regret to have to record the death of Mr. H. T. Stainton, F.R.S. He died on December 2 at the age of seventy. He was indefatigable in his study of entomology, to which he made many important contributions. His chief work is "Natural History of the Tineidæ" in four languages, with many plates. His "Manual of British Butterflies and Moths" is also well known. Mr. Stainton was one of the founders of the *Entomologist's Monthly Magazine*, and remained to the end of his life one of its editors. He was for many years secretary of the Ray Society and of the Zoological Record Association, and one of the secretaries of Section D of the British Association. From 1848 he was a Fellow of the Entomological Society, of which he was at one time president; and from 1859 he was a Fellow of the Linnean Society, of which he was at one time vice-president. He was elected a Fellow of the Royal Society in 1867.

THE Chemical Society held a special meeting on Tuesday, to commemorate the death of Stas. A paper, prepared for the occasion by Prof. J. W. Mallet, F.R.S., on "Jean Servais Stas and the measurement of the relative masses of the atoms of the chemical elements," was read and discussed.

THE new Victoria buildings of University College, Liverpool, which include the Jubilee Tower, were formally opened on Tuesday. Lord Spencer, as Chancellor of the Victoria University, took part in the ceremony. At a banquet held in the evening, Mr. Bryce announced that the Queen, out of certain funds belonging to the Duchy of Lancaster, had been pleased to bestow upon the two great Lancashire Colleges a sum of £4000, to be applied in some permanent form, such as might be agreed upon by the authorities of the Colleges, particularly the principals, to commemorate the event of that day, and Her Majesty's interest in the growth of the institution.

ON Monday, at Merchant Taylors' Hall, Dr. William Anderson presented the prizes in connection with the City and Guilds of London Institute for the Advancement of Technical Education. Afterwards, addressing the students, Dr. Anderson called attention to the extraordinary advantages enjoyed by students of the present day in comparison with those within the reach of students of the past generation. In nearly all towns men and women were improving their knowledge in almost every branch of art and science to which their necessities or their inclinations led them. He had come to the conclusion that the aids given nowadays to manufactures and commerce were absolutely indispensable if England was to hold her own, and to overcome the difficulties which high-priced labour, the restrictions of the Legislature, and the interference of trade organizations imposed.

DR T. JEFFREY PARKER, F.R.S., of Dunedin, Otago, New Zealand, who is now in this country, will read a paper on the cranial osteology, classification, and phylogeny of the Moas (*Dinornithidae*) at the Zoological Society's meeting on the 14th of February.

THE committee appointed by the Board of Agriculture to inquire into the plague of field voles in Scotland have declined for the present to recommend the adoption of the plan lately carried out in Thessaly by Prof. Loeffler, who claims to have got rid of voles in that district by feeding them with prepared bait containing the germs of mouse typhus. It is thought that Prof. Loeffler may not have attached sufficient weight to other causes which have doubtless operated to reduce the swarms of voles in Thessaly, such as the heavy rains which on the low ground would flood the holes and runs of the mice. The chairman of the committee, Sir Herbert Maxwell, and the secretary, Mr. J. E. Harting, with the sanction of the Board of Agriculture and of the Treasury, are about to proceed to Thessaly for the purpose of taking evidence there and reporting.

A NEW edition of M. Alphonse Bertillon's important book on "Identification Anthropométrique" will be published in January. The book has been entirely recast and considerably enlarged. It is the result of ten years of observation, and has been prepared, not merely for the anthropometric service directed by the author, but for all who desire to have a proper comprehension of man's physical qualities. In addition to the copies intended for the use of the penal administration of the French Ministry of the Interior, a small number of copies will be reserved for persons who may desire to subscribe for them.

ON the evening of Thursday the 8th instant a deep barometric depression advanced upon our north-west coasts, and proceeded with considerable rapidity in a south-easterly direction, completely traversing Great Britain, as far as Dover, and travelling throughout its course at the rate of about 36 miles an hour. Its passage was accompanied by gales and by heavy rain or sleet, with severe snowstorms on the east coast. This disturbance passed away to the eastward, and was followed on Saturday by a fresh depression which appeared in the north-west, causing a strong gale in that district, and heavy squalls in most other parts. The changes of temperature were very

irregular, the air being warm and moist under the influence of the cyclonic systems, but cold and relatively drier in the rear of the disturbances, in Scotland the frost was at times severe, the lowest of the minima being as low as 8° in the east of Scotland. In the early part of the present week a temporary improvement took place, with a generally rising barometer and falling thermometer, but these conditions soon gave place to a fresh disturbance in the north-west, accompanied by south-westerly winds generally. The *Weekly Weather Report* for the period ending the 10th instant showed that the temperature was below the mean in all districts, the greatest deficiency being about 7° over the northern parts of the kingdom. Rainfall exceeded the mean in the north-west of England and the north of Ireland, but in all other districts it differed little from the average amount. Bright sunshine was more prevalent than for many weeks past, except in the north of Scotland, where only 5 per cent. of the possible amount was registered.

A FOREIGN OFFICE "Report on the Social and Economical Condition of the Canary Islands" (No. 246, 1892) contains some details with respect to the climate. There is no record of the freezing point having been touched at Laguna (Teneriffe), 1840 feet above the sea. At Vila Flor, also in Teneriffe, 4335 feet above the sea, the highest point where cultivation exists, the lowest temperature recorded in 1890-91 was 28°, the lowest reading at the sea level during the same period was 49°. The highest summer reading at Laguna was 104°·9 in 1885. The average maximum temperature near the sea in the summer is about 82°. The annual rainfall at Laguna is 29·4 inches, but at Santa Cruz (Teneriffe), at the sea level, it is only about 11 inches, and at Las Palmas it is as low as 8·4 inches. The greater part of the rain falls in the Monte Verde, where the vapour is carried from the sea by the trade wind. The rain generally begins early in October and ceases early in May.

THE country between the Nile and the Red Sea has not always been so barren as it is to-day. There is ample evidence that in former times bodies of cavalry from three to five hundred in number ranged without commissariat difficulties over districts which are now deserts. The Arabic names of the valleys are names for trees, and there can be little doubt that at one time the valleys abounded with the trees after which they were called. How is the change to be explained? Much light is thrown on the problem by a most interesting paper printed in the new number of the *New Bulletin*, to which it has been communicated by Mr. E. A. Floyer, F. L. S., Inspector-General of Egyptian Telegraphs. It is an extract from the report (which will be published in French by the Egyptian Government) of the expedition despatched by the Khediv to this region in 1891. The writer believes that the mischief has been done during the last twelve hundred years, and that it is to be attributed to the Arab and his camel; the camel having eaten the leaves and shoots of the trees, the Arab having converted into charcoal the stem, root, and branch. The writer is inclined to state the matter thus: So long as the valleys were all the Arab had to depend on for feeding his camels, so long he preserved his trees for his camels. But by degrees some Arabs got a footing in the Nile Valley. They hired their camels to the farmer to carry their harvest. They went back to their deserted valley and brought away the trees in form of charcoal. Thus the land was gradually made bare. If this explanation is correct—and there is evidently much to be said for it—the writer points out that a like cause may be invoked over large areas to explain, for example, the disappearance of the frankincense and spices from Southern Arabia, to explain the thousands of chariots and horsemen in Palestine, and to explain how in early times a greater fertility and population existed in many countries whose history, like that of Palestine, seems out of proportion to their present circumstances. It is a pity, by the way, that in so good

a paper nature should be spoken of as having produced in the camel "a Frankenstein." Frankenstein in the story was not the monster, but the monster's creator.

IT is by no means certain that the harm which the camel is capable of doing in Egyptian territory has even yet been exhausted. The writer of the report considers it possible that the prosperity in Egypt in which all Englishmen are rejoicing may seal the destruction of the remaining trees, and leave the country bare save of *Calotropis procera* and the plants which nourish a few sheep and donkeys, attended by herdsmen, fed by grain from the Nile Valley. "The camel," he says, "will then, having so to speak burnt its boats, be domesticated in the Nile Valley. And it is interesting to speculate as to how he will develop there. Already the massive Cairo camel is a type distinct from other camels, surpassing all in its cumbersome massive proportions."

THE December number of the *New Bulletin* contains, besides the paper on the disappearance of desert plants in Egypt, interesting sections on the Taj Gardens, Agra, Indian gutta-percha, the Gold Coast botanical station, Ramlie machine trials at New Orleans, Lord Bute's "Botanical Tables", and miscellaneous notes. Reference was made to the "Botanical Tables" in the historical account of Kew, printed in the *Bulletin* in 1891, p. 291. Since that was written the authorities at the Royal Gardens have had an opportunity, through the gracious permission of the Queen, of examining the copy in the Royal Library at Windsor, which formerly belonged to Queen Charlotte, to whom the work was dedicated. On the fly-leaf of the first volume of the Windsor copy is the following note in pencil, written by the Rev. John Glover (appointed Royal Librarian by William IV.):—"Of this work only sixteen copies were printed for presents, at a cost, it is said, of more than £10,000. This copy belonged to Queen Charlotte, and was purchased at the sale of Her Majesty's Library for, I believe, £100." There seem, however, to have been only twelve copies. The general nature of the contents is indicated in the *Bulletin*. There are nine volumes, and the work contains 654 plates, all of them apparently drawn and engraved by John Miller, an excellent German artist—Johann Sebastian Mueller, who thus anglicised his name.

CEYLON is sending to the Chicago Exhibition a complete reproduction of a Buddhist temple and many interesting specimens of ancient Sinhalese art, including, according to the *Ceylon Observer*, "exquisitely carved pillars, massive doorways and dados, beautiful windows and frescoed panellings of courts." There will also be, among other things, a display of jewellery, lace, and pottery. It is hoped that these treasures will do something to further in America "the interests of the most modern product of Ceylon, tea."

AT the recent meeting of the Congress of Americanists at Huelva, Mrs. Zella Nuttall, of the Peabody Museum of American Archaeology and Ethnology, Cambridge, Massachusetts, presented a preliminary note on the calendar system of the ancient Aztecs. Guided by a statement in a Hispano-Mexican MS. which she has recently discovered in the National Central Library of Florence, Mrs. Nuttall claims to have found the key to the Aztec calendar system. She exhibited tables showing that the Mexican cycle was 13,515 days, and that it comprised 52 ritual years (less five days at the end of the cycle), of 260 days each, or 51 lunar years of 265 days each, based on nine moons, or 37 solar years each of 365 days. At the end of the fifty-first lunar year 10 intercalary days placed the solar years in agreement with the lunar years in such a manner that the new cycle recommenced in the same solar and lunar positions as the 13,515 preceding days. Each period commenced with a day bearing one of the four names: *acatl*, *tecpatl*, *caltli*, *tachtlil*. The calendar system and tables, 14 metres long, designed to

illustrate this communication, were subsequently placed on exhibition in the Spanish section of the Historical Exhibition at Madrid. Her Majesty the Queen of Spain commanded that Mrs Zella Nuttall should be presented to her, and expressed much interest in her work.

No one expects to see the corncrake in Great Britain after the summer months. According to the *Llangollen Advertiser*, a specimen was caught last Thursday in the neighbourhood of Pentrefelin, Llangollen. Several local naturalists have seen the bird, and agree that it is a corncrake.

A NEW luminous fungus has been forwarded to Europe from Tahiti. It is said to emit, at night, a light resembling that of the glowworm, which it retains for a period of twenty-four hours after having been gathered, and it is used, by the native women, in bouquets of flowers for personal adornment in the hair and dress. It belongs to the section "dimidiati" of the genus *Pleurotus*, in which no luminous species has been hitherto known, although there are several in the genus, and has been named by M Harriot *Pleurotus lux*. It is believed to grow on the trunks of trees.

A THEORETICAL investigation of the conditions under which Lippmann's coloured photographs are produced is given by M G Meslin in the *Ann de Chim et de Phys* for November. He maintains that the colours produced are complex, and belong to the higher orders of Newton's scale. This is illustrated by the change in colour observed when the thickness of the film increases. When moist air is blown upon it the film swells, and the bright colours give way to others consisting principally of red and green. The impure nature of the spectrum ordinarily obtained would account for its "metallic" appearance. Besides, there is a blue or greenish blue region which extends beyond the red end of the spectrum. The composite nature of the colours reflected from the surface of the spectrum photograph may be shown by projecting a similar spectrum upon the film. The colours will then appear very brilliant. But if, for instance, the green is projected upon the red of the film, green is reflected all the same, although less distinctly than before. The same thing happens in other parts of the spectrum. On moving it from the violet towards the red, the violet, arriving at the green portion, is interrupted by a broad band. On further displacement this band, the breadth of which is about equal to the distance between the E and the b lines, moves through the green and yellow and reaches the red. At this moment the blue and violet regions show the greatest brightness. There is only one band observed throughout. This observation is in accordance with the thickness attributed to the layers, viz. between 200 and 350  $\mu$ . Hence the paths traversed by the light will range from 400  $\mu$  to 700  $\mu$ , giving  $\frac{\lambda}{2}$  for none of the colours,  $\frac{3}{2} \frac{\lambda}{2} = 600 \mu$  for the violet, 650  $\mu$  for the blue, and 700  $\mu$  for the green. It will be still greater, i.e.  $\frac{3}{2} \frac{\lambda}{2}$  for the red, in the infra red region of the spectrum. There we shall have a black band in the red, while the blue is at its maximum, owing to the retardation being equal to two wave-lengths. Hence the blue region beyond the red corresponds to the infra red region of the incident spectrum, which in long exposures is able to produce a photographic effect.

DURING the year 1891 about 450 more persons were killed by wild beasts in India than during the preceding year. The number in 1890, however, was abnormally low, and the *Pioneer* calculates that last year's figures were about 250 in excess of the mean. In one district of Bengal—Hazaribagh—no fewer than 203 deaths were due to a single brood of man-eating tigers. The yearly average of persons destroyed by wild beasts is between 2500 and 3000. The

mortality from snake-bite is on a much larger scale. Year by year it varies from something over 21,000 to something over 22,000.

AN excellent account of the Experiment Stations established in the United States in the interest of agriculture is given by Mr R Warrington, F R S, in a paper issued by the National Association for the Promotion of Technical and Secondary Education. A fully equipped Experiment Station, he says, is a large and costly piece of machinery, embracing many departments of work. There is one in every State of the Union, and in some States there are more than one, the total number is fifty-four. These Stations are endowed by Congress, £3000 a year being paid to the Station or Stations of each State. If the income derived from the State Legislatures, and from other sources, be included, the average income of each Station is nearly £4000. In nearly every instance the station is connected with the State Agricultural College, and the Station buildings are in its immediate vicinity. The publications of the Stations are made in the form of periodical bulletins and annual reports, for the printing of these a special grant is made by the State, and they are distributed by the Federal Government post free. The issues are very large. 60,000 copies of each Station bulletin are printed in Ohio. Any farmer in the State can at his request receive the bulletins regularly without payment. Mr Warrington expresses a hope that our own County Councils may be encouraged to try to do for agriculture in Great Britain what is so energetically done for it in America by the various States.

A SERIES of investigations on soils is in progress at the Maryland Agricultural Experiment Station, in co-operation with the U.S. Department of Agriculture and the Johns Hopkins University. So far the work has been on the physical structure of the soil and its relation to the circulation of soil water, and the physical effect of fertilizers on soils as related to crop production. The surface tension of various solutions was first of all determined. The solutions chosen included common salt, kainit, superphosphate of lime, soil extract, and ammonia. The soil extract was made by shaking up a little soil with just sufficient water to cover it. The water was afterwards filtered off and used for the determination. This operation reduced the surface-tension of water considerably, but the experiments do not appear sufficiently complete to indicate reasons for this. Analyses of the soils are not given. Ammonia and urine lowered the surface-tension of water considerably below that of the soil extract, and still more below that of pure water. Common salt and kainit increase the surface tension of water, and no doubt this is the reason why the application of these substances to the soil tends to keep it moist, whereas the excessive use of nitrogenous manure has the reverse effect.

THE Chamber of Commerce at Reims has published the statistics of the trade in champagne since 1844. In 1844-45 the value of the trade was 6,635,000 francs, and in the following year it exceeded seven millions. In 1868-69 it amounted to nearly sixteen millions, but fell to nine millions in 1876-71, and then rose in 1871-72 to twenty millions. The value in 1872-73 was twenty-two millions, and it oscillated between this sum and seventeen millions until 1889-90, when it became twenty-three millions. The figures were 25,776,000 in 1890-91, 24,243,996 in 1891-92. The number of bottles used in France rose from 2,225,000 in 1844-45 to 4,558,000 in 1891-92, while the number exported rose during the same period from 4,380,000 to 16,685,900. The year in which most bottles were sent abroad was 1890-91 (nearly twenty-two millions).

MESSRS SWAN, SONNENSCHN AND CO have issued a translation, by Dr E. L. Mark, Professor of Anatomy in Harvard University, of the third edition of Dr Oscar Hertwig's

"Lehrbuch der Entwicklungsgeschichte des Menschen und der Wirbelthiere." The volume is entitled "Text-Book of the Embryology of Man and Mammals." The translator, in his preface, expresses his belief that the work "covers the field of vertebrate embryology in a more complete and satisfactory way than any book hitherto published in English."

THE latest instalment of the Proceedings of the Academy of Natural Sciences of Philadelphia contains a valuable paper, by Prof. E. D. Cope, on the Batrachia and Reptilia of North Western Texas. The statements presented in the paper are based on collections made along the eastern border of the Staked Plain of Texas, between Big Spring (on the Texas Pacific R. R.) on the south, and the Salt Fork of the Red River, near Clarendon (on the Denver and Fort Worth R. R.) on the north, a distance of about 250 miles. The collections were made incidentally to geological and palæontological explorations conducted by a party of the Geological Survey of Texas, which was under the direction of Mr. William F. Cummins. While attached to this party Prof. Cope picked up such specimens as came in his way, and a good many others were obtained by Mr. Cummins and by Mr. William L. Black of the party. The total number of species enumerated is thirty-three. The paper may be regarded as supplementary to one published as Bulletin 17 of the U. S. National Museum in 1880, on the Zoological position of Texas.

THE following are the lecture arrangements at the Royal Institution before Easter.—Sir Robert Stawell Ball, six lectures (adapted to a juvenile auditory) on astronomy, Prof. Victor Horsley, ten lectures on the brain, the Rev. Canon Ainger, three lectures on Tennyson, Prof. Patrick Geddes, four lectures on the factors of organic evolution, the Rev. Augustus Jessopp, three lectures on the great revival—a study in mediæval history, Prof. C. Hubert H. Parry, four lectures on expression and design in music (with musical illustrations), the Right Hon. Lord Rayleigh, six lectures on sound and vibrations. The Friday evening meetings will begin on January 20, when a discourse will be given by Prof. Dewar on liquid atmospheric air, succeeding discourses will probably be given by Mr. Francis Galton, Mr. Alexander Siemens, Prof. Charles Stewart, Prof. A. H. Church, Mr. Edward Hopkinson, Mr. George Simonds, Sir Herbert Maxwell, Bart., the Right Hon. Lord Rayleigh, and other gentlemen.

THE micro organism which has been shown to be the exciting cause of tetanus or lockjaw is just now especially attracting the attention of bacteriological investigators. Kitasato, who it will be remembered was the first who successfully isolated the bacillus of tetanus, has been continuing his researches on the protective inoculation of animals against this malady. In the current number of the *Zeitschrift für Hygiene* appears an account of some extremely interesting results which he has obtained with mice and guinea-pigs. In his experiments Kitasato introduced subcutaneously into these animals small splinters of wood which had been previously soaked in bouillon-cultures of tetanus, so prepared that only the spores were present. He wished in this way to imitate as nearly as possible the actual manner in which tetanus is communicated, and which in consequence of the sensitiveness of the bacillus to heat and light and the extremely refractory nature of the spores, is almost invariably due to the accidental introduction of the latter. This theory is also supported by the fact that between the infliction of the wound and the development of symptoms of tetanus there is invariably a distinct lapse of time, during which the spores grow into bacilli and elaborate their toxic products within the system of the animal affected, after which the typical appearances of tetanus arise. The protective material used in these investiga-

tions was the serum of a horse artificially rendered immune against tetanus, and in every case out of those mice which had received a small wood-splinter two were put aside and not subsequently inoculated with the protective serum. Kitasato found, as he had expected, that a definite period of time elapsed between the introduction of the splinter and the development of tetanus symptoms, but with hardly an exception, all those mice subsequently treated with the serum recovered, whilst those which had received no protective treatment died exhibiting the typical characteristics of tetanus. Moreover, it was found that the earlier the application of the serum took place after the infection and quite irrespective of the appearance of any signs of tetanus, the more successful was the result and the smaller the dose of serum necessary, whilst when the wood splinters and the serum were introduced together no symptoms whatever of tetanus declared themselves. The same successful results were obtained in the case of guinea-pigs. In connection with the excessively hardy nature of the spore-form of tetanus, Herviejeau (*Ann. de la Soc. méd. chir. de Liège*, 1891) has found that even after eleven years such spores still retain their power for mischief. A small fragment of wood was extracted from the ankle of a child who had died of tetanus, and after being kept for nearly eleven years part of it was introduced under the skin of a rabbit, which afterwards died of tetanus. The infection was further confirmed by the discovery of tetanus bacilli in the pus of the wound.

THE chloraurates and bromaurates of cesium and rubidium have been prepared by Messrs Wells and Wheeler, and are described in the current number of the *Zeitschrift für Anorganische Chemie*. They are all four beautifully crystalline substances. The crystals, which have been measured by Mr. Penfield, belong to the monoclinic system, and form an isomorphous series of identical habitus. These salts are so comparatively insoluble in water that they are obtained in the form of crystalline precipitates when concentrated solutions of chlorides or bromides of cesium or rubidium are mixed with strong solutions of chloride or bromide of gold. They are, however, sufficiently soluble to admit of recrystallization from water. The crystals of cesium chloraurate,  $\text{CsAuCl}_4$ , exhibit an orange-yellow colour, those of the corresponding rubidium salt,  $\text{RbAuCl}_4$ , possess a more deeply orange tint, while the two bromides,  $\text{CsAuBr}_4$  and  $\text{RbAuBr}_4$ , are jet-black but yield a dark red powder upon pulverization. The cesium compounds are much less soluble than the rubidium ones, so that the crystals are usually much smaller. The more soluble rubidium salts readily form very large crystals; the chloride in particular yields crystals whose size appears only to be limited by that of the crystallizing vessel and the depth of the solution. The crystals, however, whether large or small, all partake of the same character; they are elongated prisms terminated by the basal plane, orthodome, clinodome, and small pyramidal planes. The faces are usually extremely brilliant, but those of the bromides are often singularly hollow or cavernous. In addition to this well defined series, another chloraurate of cesium has been obtained containing water of crystallization. This salt,  $2\text{CsAuCl}_4 \cdot \text{H}_2\text{O}$ , is formed when a large excess of gold chloride is present compared with the amount of cesium chloride. It separates in the form of light orange-coloured tabular crystals belonging to the rhombic system, which exhibit the peculiar property of undergoing an internal change accompanied by elimination of the water of crystallization, within a few minutes of their removal from the mother liquor. The change is probably due to the passage of this hydrated salt into the relatively more stable anhydrous chloraurate described above. It betrays itself in a most interesting manner under the microscope, in polarized light. When a crystal plate is removed from the mother liquor,

rapidly dried by means of blotting-paper and placed under the microscope, the Nicols being crossed, it simply produces the usual effect of causing the field to become coloured with some homogeneous tint. But after the expiration of three or four minutes the molecular change begins to be rendered apparent at the circumference of the field by a rapid augmentation of the polarizing effect. In another moment it commences to dart across the field in all directions, the brilliantly coloured rays being feathered with offshoots, reminding one of the rays of crystallizing ammonium chloride. This beautiful effect continues until, in less than ten minutes after the removal of the crystal from the mother liquor, the rearrangement of the molecules has become so general that light is no longer able to penetrate, and the crystal becomes completely opaque. Messrs Wells and Wheeler have also attempted to prepare the analogous compounds containing iodine, but have not yet obtained them in a condition so pure or well crystallized as the salts described above.

THE additions to the Zoological Society's Gardens during the past week include a white-fronted lemur (*Lemur albigularis* ♀) from Madagascar, presented by Mr M. C. Parker, a brown capuchin (*Cebus fatuellus* ♂) from Brazil, presented by Mr Earle Tudor Johnson, a large-eared fox (*Otocyon megalotis*) from Mashonaland, South Africa, presented by Mr B. B. Weil, two black-backed jackals (*Canis mesomelas*) from South Africa, presented by Capt. Ralph H. Carr-Ellison, a common fox (*Canis vulpes* ♀) from Arabia, presented by Miss Morgan, a leadbeater's cockatoo (*Cacatua leadbeateri*) from Australia, presented by Lieut.-Colonel Warton, a Rhesus monkey (*Macacus rhesus*) from India, deposited.

### OUR ASTRONOMICAL COLUMN

COMET HOLMES (NOVEMBER 6) —The following is the ephemeris for Comet Holmes for the ensuing week —

1892	R. A. (app.) h m s.	Decl. (app.) ° ' "	Log $r$	Log $\Delta$
Dec. 15	0 49 34	+34 50 1		
16	50 15	45 8	0.4004	0.2813
17	50 57	41 6		
18	51 41	37 5		
19	52 27	33 6		
20	53 14	29 8	0.4027	0.2931
21	54 3	26 1		
22	0 54 53	+34 22 6		

Owing to the extremely bad weather, observations of this comet have not been numerous, but from all accounts not much change has taken place in the general appearance, except that the central nucleus seems to possess two small tails, which extend towards the ragged edge of the exterior portion.

COMET BROOKS (NOVEMBER 20, 1892) —Last week the only ephemeris of this comet at hand was one showing its position every fourth day, but Prof. Kreutz has now communicated to *Astronomische Nachrichten*, No. 3132, a daily ephemeris, from which the following is extracted —

1892	R. A. (app.) h m s.	Decl. (app.) ° ' "	Log $r$	Log $\Delta$	Br.
Dec. 15	13 50 10	+31 57.3			
16	54 6 ..	33 17.2	0.0974	0.0001	3.67
17	58 19 ..	34 41.2			
18	2 53 ..	36 9.5	0.0946	9.9775	4.13
19	7 51 ..	37 42.2			
20	13 17 ..	39 19.3	0.0921	9.9550	4.63
21	19 13 ..	41 0.8			
22	25 46 ..	42 46.6	0.0898	9.9332	5.17

From the column showing the brightnesses it will be seen that a considerable increase in this comet is taking place. The comet will be easily found by the fact that it lies in the prolongation of a line joining  $\beta$  and  $\gamma$  Bootis (December 18) at a distance equal to that between those two stars.

NO. 1207. VOL. 47]

THE NEW BROOKS' COMET —The following positions of this comet are reported from Marseilles, by MM. Esmlol and Fabry —

Date	Marseilles Mean Time h m s.	App. R. A. h m s.	App. P. D. ° ' "
Nov. 24	17 45 16	13 3 14.6	74 51 33
24	17 6 53	13 4 39.39	74 33 18.1
29	16 43 46	13 11 1.76	72 11 46.7
30	16 41 49	13 12 45.77	71 34 49.0

The comet presented the appearance of a nebulosity about 1' in diameter, diffuse at the edges, and brighter towards the centre, but without a well defined nucleus. Its brightness was about that of a star of eleventh magnitude.

NOVA AURIGÆ —Nova Aurigæ has again increased in magnitude, observations showing that visibly it is 8.5, while photographically it is three magnitudes fainter.

ASTRONOMY AT COLUMBIA COLLEGE, U.S.A. —The latest number of the bulletin issued by this college informs us that with the consent of the governing body of the New York Hospital and the college trustees, a new but small observatory is about to be erected on the site Bloomingdale. The instrument, which is at present being constructed by Wauschaff, at Berlin, is a zenith telescope, and it is one of a pair which is going to be used for observations to obtain accurate determinations of the variations of terrestrial latitudes. The other instrument, by order of the Italian government, is going to be mounted at the Royal Observatory of Capodimonte. Both instruments will soon be, if not already, in working order, the observers in America are Prof. Rees and Mr. Jacoby, while M. Higola will undertake the Italian observations.

The library of this college has been recently very much increased by the purchase of the fine library of astronomical and physical works belonging to Mr. Struve, former director of the Pulkowa observatory. This addition amounts to no less than 4361 bound and unbound books, together with 3056 pamphlets.

COMPANION TO THE OBSERVATORY FOR 1893 —This annual Companion for the coming year is very similar to the one last published. Mr. Denning gives a list of the principal meteor showers deduced from recent observations, while ephemerides for the planets, together with their satellites, are also inserted. Solar observers will find the ephemeris given on page 22 very useful, this table giving the position-angle of the sun's axis, and the heliographic latitudes and longitudes of the centre of his disc. In addition to several other handy tables and ephemerides, the times of minima of variable stars not of the Algol type, variable stars of the Algol type, maxima and minima of variable stars, and finally a table of double stars are also included.

### GEOGRAPHICAL NOTES

MAJOR THYS, who has recently returned from the Congo Free State, reports that the railway from Matadi to Stanley Pool is progressing rapidly. The works are practically completed for only 14 kilometers out of the 400, but this includes the most difficult region, including the greater part of the ascent to the plateau. In a few months it is hoped that 40 kilometers will be completed, and the malarial coast-belt can then be traversed rapidly, obviating a serious risk to the health of travellers to the Upper Congo.

WE are pleased to find that the Manchester Geographical Society has published the concluding part of the seventh volume of its Journal although, as we had occasion to remark on the appearance of the previous part, it is greatly to be regretted that the people of Manchester do not take a greater interest in a Society which is one they have reason to be proud of. It is, we are convinced, solely to this want of local appreciation that the Journal has to be issued so far behind its proper date as to impair the usefulness of its contents. In the current number there is an interesting paper on Japan by Mr. W. M. Steinthal.

MR. G. A. CRAIG has, we understand, resigned the secretaryship of the Liverpool Geographical Society on account of ill-health.

THE *Scottish Geographical Magazine* for this month contains a paper by Captain Lugard, entitled "Characteristics of African

Travel" The Society presented Capt. Lugard with its silver medal and an honorary diploma of Fellowship. A similar award has been made to Mr. Joseph Thomson in recognition of his services to Geography in Africa.

DR. J. TROLL, an Austrian explorer, is at present engaged in a journey through Central Asia. He reached Samarkand in the end of October. Thence he proposes to pass through Russian and Chinese Turkestan and Mongolia, intending to return by Peking and Shanghai. In the course of his journey he hopes to visit the ruined city of Karakoram, the ancient capital of Jenghiz Khan.

A RAILWAY has recently been opened from Wiborg, in Finland, to the Imatra Falls, thus bringing the finest rapids in Europe within six hours of St. Petersburg. Hitherto the falls have been reached by canal-steamers and coach, the journey occupying not much less than twelve hours.

MR. JOSEPH THOMSON proposes to use the name "Livingstonia" to describe the whole British sphere of influence north of the Zambezi and west of Lake Nyasa. It is little to the credit of British cartographers that the attempts hitherto made to associate Livingston's name with the continent of which he was the greatest explorer have practically failed.

### THE DESTRUCTION OF IMMATURE FISH

MR. ERNEST W. L. HOIT contributes to the new number of the Marine Biological Association's Journal another very interesting paper on the results of his North Sea Investigations. He has much to say as to the destruction of immature fish in the North Sea, and makes the following observations on proposed remedial measures—

It will be admitted that the continued destruction of large numbers of valuable fish before they have had a chance of reproducing their species can only result in increased deterioration of the industry, and that some measures must be taken to put a stop to it unless we are prepared, and able, by artificial propagation to restock the sea as fast as we deplete it. Briefly the various proposals that have been put forward fall under three headings, viz. closure of grounds frequented by small fish, restriction of sale of undersized fish, and enlargement or alteration of mesh. We have seen that some of the smack-owners have adopted the eminently practical method of forbidding their boats to fish where they are likely to catch much small stuff; but the buyers, though as loud as any in their outcry, do not appear inclined to avail themselves of their undoubted power to check the evil. The proposals for legislative action have been so much discussed of late that I need only advert to such as affect the North Sea district.

It is a matter of common knowledge that the bulk of the destruction by deep-sea trawlers takes place on the eastern grounds, to which I have alluded elsewhere, and since these lie wholly or in part outside the three-mile limit, it has been proposed that they shall be closed to trawling by international agreement. Whether such agreement could ever be arrived at is questionable and if it were, it is not likely that the ensuing legislation could be easily enforced. The great extent of the grounds would involve an enormous and costly Marine Police force, of mixed nationality, and even were such a body much more efficient than one has any reason to expect, there might be considerable difficulty in adequately watching grounds which extend in some cases over fifty miles from shore. Indeed, on our own coasts and elsewhere the success with which legislation limited to the territorial area has hitherto been enforced is hardly such as to encourage us to extend the principle to the open sea.

The various standards of size which have been advocated, in proposals for prohibiting the sale or possession of undersized fish, differ according as the subject has been treated with regard to the marketable qualities of the fish, or to its powers of reproduction; and it may be assumed, I suppose, without argument that the latter is the more rational method of treatment. Still it may be as well to recapitulate the sizes proposed at the Fishery Conference at Fishmongers' Hall last February, since they may be taken to represent the most recent trade opinion on the subject.

They are for turbot and brill twelve inches, for soles and lemon sole (*Pleuronectes microcephalus*) ten inches, and for plaice eleven inches. How far they fall short of the biological limits, at least for the North Sea district, can be judged by comparing them with the table of sizes on p. 384 of the Journal, and, indeed, I may remark that the prohibition of the sale of

turbot and brill under twelve inches in length is rather a work of supererogation, since the number of smaller fish of these species that come to market, at all events at Grimsby, is utterly insignificant.

The benefit to be expected from any measure of prohibition depends of course on the vitality of the fish, and it is very generally asserted that the bulk of the small fish trawled on these eastern grounds would not survive if returned. My own experience leads me to believe that this view is correct<sup>1</sup> so long as the present system of long hauls is maintained. Hence we must seek for such a limit as will render the grounds most frequented by these small fish unprofitable to the fishermen (since any less limit would only involve an infinitely greater waste than takes place at present), and in doing so it is necessary to glance at the general conditions of this fishery.

Exclusive of less important forms, the species chiefly met with are plaice, turbot, and soles. The plaice, on most grounds, do not exceed a length of fifteen inches, and are mostly less than thirteen inches in length. The turbot are fairly abundant, but, as I have already shown, almost all immature, soles are scarce. It is only the certainty of being able to fill up with small plaice that induces the fishermen to cross to the eastern side, since the soles and turbot would not nearly pay his expenses by themselves. Now I am confident that if the Conference limit of eleven inches for plaice were enforced, there would still be enough saleable fish left to make the grounds worth visiting, whereas if it were raised to fifteen or even fourteen inches the grounds would assuredly be left alone, and although such would be below the biological limit, I believe the practical closing to our huge fleets of such a magnificent nursery for young plaice would be in itself a sufficient protection for the species. Certain rough patches of ground, practically surrounded by areas yielding only small fish, abound with only large fish, these would still be accessible to fishermen, whereas in any scheme of geographical restriction it would hardly be possible to exempt them. Moreover the restriction of size would probably do away with the destruction of small plaice by shrimp or sole-trawls, since the fish are not injured by being caught in these nets, and if unsaleable<sup>2</sup> would probably be returned.

For turbot, brill, and sole I would advocate the adoption of the biological standards. They are all rather hardy forms, and it appears that immature brill and such immature turbot as are found on our own coasts are chiefly caught on certain banks where the intricate nature of the ground renders short hauls a necessity, so that they could be returned to the sea in good condition, as indeed the smaller of them usually are at present by many fishermen. With regard to soles, I do not think that many undersized fish are caught by deep-sea trawlers,<sup>3</sup> and the substitution of a size limit for the present prohibition of the use of a fish-trawl in the Humber would do away with the anomaly of a law which is not enforced. There is a strong feeling amongst inshore fishermen that the bye-law alluded to is unequal in its operation, since it offers no check to the destruction of small fish on off-shore grounds, only accessible to large boats. Hence a regulation as to the size of fish landed is perhaps preferable to one based solely on territorial conditions somewhat imperfectly understood.

An objection which I have heard urged against any scheme for keeping our trawlers off the eastern grounds is that the summer sole trade in the North Sea would thereby be left entirely in the hands of foreigners. I think that this is, perhaps, rather overstating the case, but anyhow I cannot see that it furnishes any excuse for the present enormous destruction of small plaice and turbot, whilst it is at least possible that the abatement of our own fleet from these grounds in the summer would result in a corresponding increase in the number of soles in the localities where that species congregates in the winter months. I have no knowledge of the migrations of soles, but the Great Silver Pit is equidistant from the Humber and the nearest eastern ground, and as it is the nearest point at which similar physical conditions can be attained, it does not seem improbable that the winter supply of soles in the Pit is in part recruited from the east side of the North Sea.

<sup>1</sup> Owing to the great mass of fish caught in a single haul, I consider it quite possible to hold this view without throwing any doubt on the value of the results obtained by my friend Dr. Fulton in his experiments on the vitality of trawled fish (Report S. F. B., 1891).

<sup>2</sup> The possession, as well as the sale, should be prohibited, to guard against the possible danger of small fish being utilized as manure when the fishermen are also a farmer in a small way.

<sup>3</sup> The small soles caught on the Dogger and on the Dowling are really solanetes (*Solea melanota*).

Another objection is that boats of British nationality are not the only ones engaged in the small fish trade, and it is true that during the summer months a number of German, Dutch, and Danish boats are occupied in catching small plaice. But they are all of small tonnage, some of them only open boats, and I understand that from the manner in which the trawl is handled by German and Danish boats no injury is done to the unmarketable fish, whilst the saleable part of the catch appears to be exported chiefly to London. Hence the proposed measures of prohibition would give no advantage to these nations. The German steam trawlers, according to my information, do not molest the small plaice at all. Of the proceedings of the Dutch bombs I have little knowledge, but from the small size of their gear, their share in the destruction cannot be a very large one. Foreign caught fish, except Norwegian salmon and mackerel and Dutch soles, including only a small percentage of undersized fish, rarely come to the Grimsby market, but on two occasions large consignments of small plaice, comprising, as I compute, some 31,000 fish, were sent from Denmark, and recently a consignment of turbot has arrived from Norway. These last fish were about 300 in number, all undersized, viz. from 9½ to 17 inches, whilst 4 were only from 8 to 9 inches. This is the only instance which has come under my notice of any considerable number of turbot less than 12 inches being present in the market, and, as we have seen, our own fishermen were not concerned in it.

The last and perhaps the most important objection arises from the difficulty in allowing for that variation in the size of fish of the same species on different parts of our own coast to which Mr Calderwood alluded in the last number of the Journal, p. 208. The impossibility of utilizing a uniform size limit for all districts sufficiently exemplified by the limit of 11 inches for the plaice proposed by the Conference of last February, which was the result of a compromise between the trade representatives of the North Sea and south and west coast districts. While perhaps unnecessarily high for the Plymouth district, we have seen that it is altogether too small for the North Sea. The difficulty of having different limits, of local application, will only be felt at such a central port or market as London, to which fish are brought, whether by rail or sea, from all districts, but with proper organization the obstacle does not seem insuperable. It is conceivable that the law might be evaded by running cutters from boats fishing in one district to the parts of another, where the limit was lower, but it is little likely that the firms which are in a position to undertake them, would lend themselves to such operations. There is not the slightest reason to apprehend a general conspiracy of evasion amongst the fishermen, and the boats which respected the law would form a more efficient police than all the cruisers in the navy, so far as one may judge by the conditions on the Scotch coast, where convictions of trawlers for infringement of the territorial restriction are frequently secured by the evidence of local line fishermen.

I must leave to others, who are acquainted with the local conditions, to decide whether the imposition of a size limit is desirable in other districts, but for the North Sea I have not the slightest hesitation in recommending this method of legislation, in the terms I have proposed above, as cheaper and likely to be infinitely more efficacious than any other that can be devised in maintaining the supply of the more important kinds of flat fish. I need hardly observe that its application to the halibut, which is chiefly a line fish, could not fail to be beneficial to that species, since there is no question but that fish caught on the hook will usually survive if returned, but I do not think that the limit need be as high as the biological one, owing to the difference in the conditions of the trawl and line fisheries.

I am not prepared to enter at present into the question of mesh legislation, beyond pointing out that it appears to be the only method by which the destruction of immature round fish, notably haddock and whiting, can be checked, since these species are fatally injured by being caught in the trawl, and would not survive if returned. Any great enlargement of the mesh does not appear advisable, since it would afford an opportunity of escape to the mature sole, of which that active species would be extremely likely to avail itself. The remedy seems to lie rather in an alteration of the arrangement of the meshes in the cod-ends, so as to prevent them from closing. On this subject I have been making investigations, but they are not yet sufficiently complete to yield reliable deductions. It is sufficiently evident, as has often been pointed out, that the great breadth of some of

the flat-fish render it impossible to deal with the whole question by restrictions of mesh alone.

The last matter with which I have to deal is the destruction of very small fish by shove-net and shrimp "seines." If it were only possible to induce the men to cull out the small fish in the water they would do no harm at all, and practically I suppose that, as matters are, they do not greatly injure any species of known value except the plaice, although the small number of sole, turbot, and brill destroyed may represent, from the relative scarcity of these species, a more considerable injury than one would suppose. When fishing by day the shove-net men usually return the fish to the sea, but by night this is impossible, and the seine men do not seem to make any effort in that direction either by day or night.

It is a difficult question to deal with, since the shrimp appears to be almost a necessity to some people, at the same time the small plaice which are destroyed must represent an infinitely greater value than the shrimps. If hatcheries were established, and young turbot, brill, sole, and plaice were enlarged after they had been reared through the delicate larval and metamorphosing stages, it is reasonable to suppose that they would be conveyed or would find their way to the sandy margins, which seem best adapted to the succeeding stages of their life-history, only to fall into the net of the shrimp.

I should say that to prohibit the use of any sort of shore shrimp nets during night-time would be a beneficial measure, but there is perhaps sufficient reason for abolishing the industry altogether. Those engaged in it might be sufficiently compensated at a moderate expenditure, if indeed it be not contrary to public policy to admit the existence of a vested interest in an occupation which is essentially injurious to industries affecting a much greater section of the community.

### THE NEW TELEPHOTOGRAPHIC LENS

IN a small pamphlet of thirty pages, written and published by Mr T R Dallmeyer, the author brings together the various notices bearing on the subject of his new telephotographic lens that have appeared during the last twelve months. He also gives an account of the "simple" and "compound" telephotographic lens, with general instructions for their use, including tables of their properties, and a table showing the diameters of circles of illumination necessary to cover the various sized plates used at the present day.

The telephotographic lens is, we may say, the latest advance made in the science of optics as applied to photography. By it we are now able to obtain large pictures of animate things situated at long distances with short exposure. In this invention Mr Dallmeyer has produced a useful, and what may prove a valuable, instrument, and he has opened up quite a new horizon which will not suffer from lack of workers.

Hitherto the principle involved in the apparatus for the production of large images consisted first in obtaining the primary image, and second in subjecting this image to the process of enlargement. To obtain the former a concave mirror, or more generally double convex lens, has been employed, while the subsequent magnification has been produced by placing a secondary magnifier or second positive lens behind the plane of the primary image.

This method, except in the case of astronomical work, has not been, we may say, popularly used, for the cumbrousness of the apparatus required, and the length of time necessary for exposure have quite prohibited its use for anything but inanimate subjects.

It is well known that the focal length of a lens is measured for practical purposes from the principal plane passing through one of the nodal points nearest the principal focal plane to that plane. In most lens-constructions this nodal point lies within the lens-mount. Now it will be seen that if this nodal point could be thrown in front of the lens, that is, on that side away from the focus, the focal length, if measured from the lens, would be shorter. This is exactly what Mr. Dallmeyer has done. In the simple telephotographic lens the anterior element, which is of large aperture and short focus, is a positive lens, while the posterior is negative, and of a fractional part of the focal length of the former lens. A diagram showing the lenses in position and the path of a ray of light remind one at first sight of the principle of the Galilean telescope, with this difference, that the rays emerging are not divergent, but convergent. In the construction

\* Shrimp fish with air-bladders, caught at considerable depths.

under consideration the size of the image thrown on the screen can be varied at will by simply altering the distance between the elements, but the further the lens is from the focussing screen, the more will be the time of exposure.

With such a lens as this Mr Dallmeyer has taken many excellent pictures, but perhaps the best idea of its properties will be gathered from the facts obtained by photographing—by means of two cameras, one supplied with a "long focus landscape lens," and the other with the "new telephotographic lens"—the flame of an oil lamp placed at a distance of 20 feet. With equal extensions of the camera the image of the flame given by the new lens was five times greater than that by the other.

In the compound lens the anterior element before referred to is here replaced by a complete portrait lens, while a negative symmetrical combination takes the place of the posterior element. This lens may be said to be more perfect than the simple lens, Mr Dallmeyer having been able to introduce considerable improvement in the construction.

Some excellent work done with this lens has been exhibited by Messrs F Mackenzie and Annan at the Camera Club. The pictures represented a building at a distance of 500 yards. The first, taken with an ordinary rapid rectilinear lens with an extension of 14 inches, gave the house as  $\frac{1}{3}$  of an inch long. The second—with the compound tele photo lens, extension 9 inches from the back lens—gave  $2\frac{1}{2}$  inches as the size of the house, while the third, with 30 inches' extension, gave the house as  $6\frac{1}{2}$  inches. Although these numbers can give one a very good idea of what this new lens can accomplish, yet the direct copies from photographs inserted in the pamphlet under consideration convey a more vivid impression.

There is no doubt that this lens will find some very valuable applications, that of astronomical photography not being the least of them, for every one knows the great advantage a short telescope has over a long one if the degree of magnification in both are equal. W

#### ARBORESCENT FROST PATTERNS

WE have received the following letters with regard to arborescent frost patterns, to which Prof Meldola called attention in last week's NATURE—

I AM very glad that Prof Meldola has called attention to the curved figures of frozen mud (of which the specimens on December 4 were unusually fine), because I hope that some one will explain why the hexangular crystallization which is universal in snow, and general in water, is exchanged both on windows and on muddy pavements for curves. Probably I ought to know all about it, but I cannot remember seeing an explanation, and shall be obliged by reference to one, which will probably be of interest to others besides. G J SYMONS

62, Camden-square, London, N W

THE interesting "fronds" of muddy ice observed by Prof. Meldola (p 126) are not very uncommon on the pavements in these "Northern Heights." I saw them on the date which he named, and have more than once studied them. I then noticed that the "interstitial" pavement seemed partly cleared of mud, as if the water had drawn this towards the groups of crystals. The mode of formation recalled to my mind certain phenomena in crystal building within rocks, and I suspect the mud has its influence. Indeed, it seems to me very probable that all these "dendritic" growths of crystals are the results of "impeded" or "constrained" crystallization, to some of which I have called attention in noticing a structure in the Charnwood syenite (*Quart Jour Geol Soc*, 1891, p 101). On this point Prof. Sollas makes some important remarks in his well-known paper on the Wicklow granites. T G BONNEY

THE beautiful curved forms assumed by the ice on the paving flags last Sunday were very noticeable in this neighbourhood and Hampstead as well as in other parts of London. What I observed were not quite like those described and figured by Prof. Meldola, but resembled rather the scrolls and volutes which are frequently used in decorative art. The finest piece that I saw was in this square, where several of these scrolls radiated from a central point, and spread over several feet of the pavement. A friend, Mr. E. Swain, observed that where one of these scrolls came upon a paddle of clear water the crystals were continued in a straight line. Such forms are not at all unusual in the freezing of muddy water, and at the present moment the puddles in the road opposite my house are

filled with rectilinear crystals of ice, which assume a curved form in the mud at their margins. The peculiarity on Sunday was their large size and beauty. Something analogous takes place when gold or silver is reduced from solutions of its salts by more electro positive metals. Under certain circumstances

the metal will present itself in the form of curved crystals, if the term be allowable. A pretty spray of gold of this character is figured in the report of my lecture "On the crystallization of silver, gold and other metals," in the proceedings of the Royal Institution, vi, 428. If a piece of cuprous oxide be immersed in a solution of nitrate of silver, there shoot from its surface thin threads of silver, which, after proceeding straight forward for a while, suddenly turn at an angle of 120° or 60°, and make perhaps many other deviations but sometimes these threads, instead of being straight, are curved, and in that case the threads that branch from them are curved likewise. A magnified drawing of such a formation is given herewith. These strange departures from the usual rectilinear course of crystal formation are very curious, and deserve more study than has hitherto been given them. J H GLADSTONE

17, Pembroke-square, December 10

PROF MELDOLA's letter (p 125) has been interesting to me, as I noted a striking and similar phenomenon here on Thursday, December 8, in the forenoon. The trottoirs of several streets (east, west, north and south) were covered all over with beautiful patterns, somewhat different from Prof. Meldola's illustration, there being innumerable dark, broad, sharply contoured leaf-like patches, distant several inches from each other, and connected by finely curved and branched tendril-like stalks. Foggy, with a faint north breeze. I should presume the "leaves" were due to sparse drops of sleet fallen during the night. Freiburg, Baden, December 10. D WETTEKIAN.

THE graceful arborescent frost patterns described by Prof. Meldola in last week's NATURE were very conspicuous on the foot-bridge by the side of Charing Cross railway bridge, on the same morning, this being a situation still more exposed to the wind which he mentions as the probable cause.

December 12.

J T. RICHARDS.

I OBSERVED the same phenomenon as Prof. Meldola describes in NATURE of December 8, on the same date, December 4, on pavements in Cheltenham, about 10.45 a.m.; after mid-day they had gone. I saw the patterns on pavements running north and south, as well as east and west. They were most exquisite; some like the illustration, others much more minute, but always in a connected design over the whole flag. They had all the appearance of fossil vegetation. I never saw anything of the kind before. J J ARMITAGE.

December 13.

MR. A. W. BENNETT and Mr. E. L. Garbett have also sent communications corroborating the phenomenon observed by Prof. Meldola. The former attributes it to "defoliation of the stones as the result of weathering or wear."

## THE MAKING OF RIFLES

AT a recent meeting of the Institution of Civil Engineers, Mr John Rigby, superintendent, Enfield Factory, read an interesting paper on the manufacture of small arms. We reproduce from the abstract printed for the Institution Mr Rigby's lucid account of the various processes of manufacture of the components of the Lee Metford Mark I magazine rifle, of 303 inch bore, the weapon adopted for the British Army—an account which he prefaced with a general description of the Enfield Factory.

The most important part of a rifle was the barrel, which had always engaged the special attention of gun-makers. Up to the time of the Crimean War, it was, for the bulk of British troops, a comparatively rude tube of iron, lap-welded under rolls and tapering externally, with a cylindrical bore of about  $\frac{3}{4}$  inch diameter. The barrel of the present day was a steel tube of accurate workmanship, only  $\frac{1}{8}$  inch bore, almost perfectly true and straight, rifled to  $\frac{1}{16}$  inch, and so closely inspected that the existence of the most minute grey or seam in the bore, requiring a highly-practised eye to detect it, was sufficient to condemn it. The material used was produced either by the Siemens-Martin or the crucible process of manufacture, and was supplied to Enfield as a solid round bar  $1\frac{1}{2}$  inch diameter and  $15\frac{1}{2}$  inches long. After severe testing, this bar was passed through a rolling mill to draw it to its full length. It was then taken to the forge, the swell at the breech-end was stamped to the required shape by a steam-hammer, and afterwards straightened cold. The next step was to submit the bar, without annealing, to the turning and drilling-machines. The latter were horizontal, the drills operating from each end. In the process of drilling, the barrel revolved at nearly 1,000 revolutions a minute against half round bits held flat down, a capillary tube, of brass, supplying a soap-and-oil emulsion, at a pressure of 80 lb to the square inch, to wash out the swarf and cool the cutting edge. The drills advancing from each end continued boring until a small disk about  $\frac{1}{16}$  inch diameter broke out, and the two holes met. The tendency of the drills to follow the line of axis of a revolving bar was one of those curious occurrences in practical mechanics which might be accounted for after observation, but which no one would predict. Occasionally, through some defect in the steel, a drill wandered from the axial line, in this case the barrel was taken from the machine and reset sufficiently to bring the hole true again. To test its truth, a ray of light was made to illuminate the flat bottom of the hole while the barrel slowly revolved. It was very rarely that a barrel was rendered waste from bad drilling. Rough-boring followed with a three edged bit, the blade being about 4 inches long. The rough external turning was effected in self acting lathes, which gave the required curved taper. Three or four cutters acted simultaneously, each producing a long cutting that attested the quality of the metal of the barrel. The operation of barrel-setting followed. Previous to rough turning, the barrels were fairly straight internally, but the removal of the metal caused slight inequalities which were tested by the eye of the barrel setter, and corrected by transverse blows. This constituted skilled labour of a peculiar character, and was performed by young men of good sight, who were specially trained for the purpose. After middle life the eye generally lost some of the quality necessary for this work, and it was rare to find a man excel in it after that period. Many mechanical devices had been contrived to supersede the simple ray of light laid, as if it were a straight edge, along the surface of the bore, but the eye still remained the arbiter of straightness and could be relied on for very accurate results. The construction of the barrel was completed by the important operation of rifling. In British small-arm factories the system was followed of planing out each groove separately with a hooked cutter, and had been brought almost to perfection in Continental and American factories the grooves were ploughed out by cutters, with several cutting or knife-edges set at an angle and following one another in the manner of a single-cut file or float. Similar machines had been tried at Enfield, but did not give as smooth a cut as the slower-moving, single-tooth machines. A few passes of a lead lap, fed with fine emery, removed any burr that might remain, and completed the polish; a cylindrical lap, rotating rapidly, was then passed through, and gave the final finish to the barrels. The limits of gauging were from  $\frac{1}{16}$  to  $\frac{1}{8}$  inch.

Next in importance to the barrel was the mechanism of the breech, for which the material preferred was crucible cast-steel

of a mild character, but capable of being hardened in those parts exposed to the pressure of the bolt. The body was forged in two operations under the steam-hammer, it was then drilled and subjected to a long series of operations, in the course of which the end was recessed to receive the screwed end of the barrel, and the corresponding thread in the recess was milled out in a specially-contrived machine, which insured that the thread should always start in the same place relative to the gauged part of the body, a point of great importance. The bolt, also of crucible cast steel, was forged under the steam hammer. A special machine, invented at Enfield, was used to finish the bolt after shaping. After machining, the bolts, packed in wood charcoal in iron cases, were heated and hardened by immersion in oil. The temper of the handle was then reduced in a lead bath. The rest of the bolt was tempered straw colour. The bolt-head was similarly hardened and tempered.

The other components of a complete rifle were mostly shaped by mills built up to the proposed profile, or by copy-milling machines. The process of drifting was used with good results at Enfield. All such slots or perforations as had parallel sides, and were not cylindrical, were so finished. The common practice in drifting was to push the drift, but at Enfield much better work was accomplished by pulling. It was found that used in this way drifts were very valuable for interchangeable work. The sides were cut with successive teeth, each slightly larger than the preceding one, and the whole length of the drift was drawn through. Emery wheels were also largely used at Enfield as a substitute for finish-milling and filing. The wheels ran under hoods connected with a pneumatic exhaust that carried away the heated particles of steel and grit. It was popularly supposed that a machine once adjusted to turn out a component of a certain size and shape was capable of reproducing such in large numbers, all absolutely identical. This was so far from being the case that no die, no drill, and no milling-cutter actually made two consecutive articles the same size. The wear of the cutters or dies proceeded slowly but surely, and it was only possible to produce in large numbers components of dimensions varying between a superior and an inferior limit. In small-arm manufacture a variation of about one two thousandth of an inch was about the amount tolerated, but it varied according to the size of the piece. A difference of diameter of one two thousandth of an inch in the sight axis-hole, and in the size of the pin or axis, would cause a serious misfit, whereas a similar difference in the measurement of the magazine, or of the recess in which it lay, would be quite immaterial. The operations of gauging, proving the barrel, and sighting, were successively described, as also the manufacture of the stock, which was of the wood known as Italian walnut, though largely grown in other countries. Among the smaller components, the screws were mentioned as being rapidly produced by the automatic screw-making machines of Pratt and Whitney.

The Component Store received the various finished parts, which numbered 1591, or, including accessories, 1863, and issued them to the foreman of the assembling shop. Theoretically, the assemblers should have nothing to do but to fit and screw them together, but in practice small adjustments were found necessary. The amount of correction was generally exceedingly small, and was done wherever possible with the aid of emery wheels. The completed arms were submitted to inspection, and then issued in cases of twenty each to the Weedon Government Store or elsewhere.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—The General Board of Studies propose that, in view of the increased attention given to palaeontology in the Geological Department, a Demonstrator in Palaeozoology be appointed, whose stipend shall be paid out of the students' fees.

The Botanic Garden Syndicate report the completion of the fine range of plant-houses, which have for some years been in course of erection at a cost of some £6000. It is noteworthy that the expense has been kept within the estimate.

The Senate has determined to raise the fee for the Doctor's degree (including M.D. and Sc.D.) from £20 to £25. It has rejected the proposal to increase the annual dues of undergraduates from 17s. to £2, and of graduates from 17s. to £1, which was put forth in view of the financial needs of the University, by the Fees Syndicate. The proposal to accept life-

compositions for the annual dues was also rejected. Dr Allbutt, Regius Professor of Physic, has been appointed an Elector to the Chair of Botany, in the place of the late Dr Hort.

The discussion on the plans for the new Geological Museum (given at length in the *University Reporter* for December 13) was highly interesting, and appears on the whole to have been favourable to the scheme proposed, subject to relatively unimportant modifications. Prof Newton objected that the arrangement of its contents should be zoological rather than stratigraphical, and the Registrary (Mr J W Clark) took exception to the plan of lighting, which would be better if it were from the top rather than the sides. The geological staff were unanimous that the plan put forward was that which best met their needs. It was agreed that the architectural effect of the museum would be very fine, and worthy of Sedgwick's memory.

## SOCIETIES AND ACADEMIES

### LONDON

Royal Society, November 24.—"Ionic Velocities." By W C. Dampier Whetbam, B A, Fellow of Trinity College, Cambridge. Communicated by J J Thomson, F R S.

From a series of determinations of the electrolytic conductivity of various salt solutions combined with Hittorf's values for the migration constants, Kohlrausch calculated the velocity of different ions under a potential gradient of one volt per centimetre. Dr O Lodge actually observed the velocity of the hydrogen ion as it travelled along a tube filled with sodium chloride dissolved in jelly, decolourizing phenol-phthalein as it went. He found 0.029 cm per sec, and Kohlrausch gives 0.030.

The author has measured the specific ionic velocity of other ions by observing the motions of a junction between two salt

solutions of slightly different density and different colours, when a current was passed across it. From the velocity of the boundary, that of the ion causing the change in colour can be deduced. The apparatus consisted of two vertical glass tubes about 2 cms. in diameter, joined by a third considerably narrower, which was bent parallel to the others for the greater part of its length. The tube was filled with the solutions in such a manner that the boundary was formed in the vertical part of the junction tube.

When the solutions are of different specific resistances there will be a discontinuity of potential gradient at the boundary and a consequent electrification. The effect on the velocity of the boundary is, however, non-reversible, and, for small differences, can be eliminated by taking the mean of the velocities in opposite directions. The direct estimation of potential gradient is unsatisfactory, but by measuring the current ( $\gamma$ ), the area of

cross-section of the junction tube (A), the specific resistance of the solution ( $\rho$ ), and the velocity of the boundary ( $v$ ) we can find the specific ionic velocity  $v$ , for  $v = \frac{\rho A}{\gamma}$ .

The first solutions used were those of copper and ammonium chlorides dissolved in aqueous ammonia, the former being blue, the latter colourless. The junction travelled with the current with a velocity of 1.57 cm per hour going upwards and of 1.60 cm per hour coming downwards. The mean gives as the specific ionic vel of Cu in solutions of 1 gram equiv. per litre 0.00309 cm per sec. This agrees exactly with Kohlrausch's number for infinitely weak solutions of 0.0031 cm per sec. Other measurements were made for chlorine and for the bichromate group ( $\text{Cr}_2\text{O}_7$ ).

The method was extended to alcohol solutions. The velocities of both ions of a salt were determined by using two pairs of solutions. Thus the velocity of chlorine was found by using a cobalt chloride-cobalt nitrate pair, the colours of which are blue and red respectively, and that of cobalt by a cobalt chloride-calcium chloride pair, these being blue and colourless. The sum of these velocities was compared with that deduced by Kohlrausch's method from the conductivity of the solution. The following are the results:—

### SPECIFIC IONIC VELOCITIES

#### I—Aqueous Solutions.

Ion	Velocity observed	Velocity calculated
Copper	0.00026*	0.00031
	0.000309	
Chlorine	0.00057*	0.00053
	0.00059*	
Bichromate group ( $\text{Cr}_2\text{O}_7$ )	0.00048	0.000473
	0.00047	
	0.00046	

\* Preliminary observations.

#### II—Alcoholic Solutions.

Salt	Vel. of Anion observed	Vel. of Cation observed	Sum of vels. observed	Sum of vels. calculated
Cobalt Chloride	0.000026	0.000022	0.000048	0.000060
Cobalt Nitrate	0.000035	0.000044	0.000079	0.000079

December 8 — "On the Velocity of Crookes' Cathode Stream" By Lord Kelvin, P R S.

In connection with his splendid discovery of the cathode stream (stream from the cathode in exhausted glass vessels subjected to electric force), Crookes found that when the whole of the stream, or a large part of the whole, is so directed as to fall on 2 or 3 sq. cm of the containing vessel, this part of the glass becomes rapidly heated up to many degrees, as much as 200° or 300° sometimes, above the temperature of the surroundings.

Let  $v$  be the velocity, in centimetres per second, of the cathode stream, and  $\rho$  the quantity of matter of all the molecules in 1 c.c. of it. Supposing what Crookes' experiments seem to prove to be not far from the truth, that their impact on the glass is like that of inelastic bodies, and that it spends all their translational energy in heating the glass. The energy thus spent, per square centimetre of surface struck, per second of time, is  $\frac{1}{2}\rho v^3$ , of which the equivalent in gramme water centigrade thermal units is approximately  $\frac{1}{42}\rho v^3/42,000,000$ . The initial rate at which this will warm the glass, in degrees centigrade per second, is

$$\frac{1}{10^8} \times \frac{\frac{1}{2}\rho v^3}{42 \sigma a} \dots \dots (1)$$

where  $\sigma$  denotes the specific heat of the glass, and  $a$  the thickness of it at the place where the stream strikes it.

The limiting temperature to which this will raise the glass is

$$\frac{1}{E} \times \frac{\frac{1}{2}\rho v^3}{42,000,000} \dots \dots (2)$$

where  $E$  denotes the sum of the emissivities of the two surfaces of the glass in the actual circumstances.

It is probable that  $\rho$  differs considerably from the average density of the residual air in the enclosure. Let us take, however, for a conceivably possible example,  $\rho = 10^{-8}$ , which is what the mean density of the enclosed air would be if the vessel were exhausted to  $8 \times 10^{-8}$  of the ordinary atmospheric density.

hand along the tube. Another series of experiments were performed in varying magnetic fields. With a view to showing Hertzian phenomena to large audiences the authors tried Geissler tubes to replace the spark-gap in resonators, with great success. When large Leyden jar circuits were used the effects were very brilliant. Another form of resonator consisted of a bent wire terminating in two plates, between which an exhausted tube was placed. This tube became luminous when the resonator was placed in the vicinity of a fairly large Hertz oscillator. Other experiments similar to those shown before the society at Cambridge by Prof. J. Thomson, on discharges in exhausted bulbs were then made, the bulbs being placed with a coil of wire of four turns, forming the connection between the outer coatings of two small jars, whilst sparks passed between knobs connected with the inner coatings. The bulbs glowed brightly at each discharge, rings of light being seen near their inner surfaces. On putting a ring tube outside the coil this was also seen to glow. The most brilliant part of the glow always occurred in close proximity to the wire coil. A secondary coil, wound by the side of the above-mentioned primary, could be short-circuited at will, this had the effect of decreasing or extinguishing the luminosity in the bulb or tube. Bright sparks passed between the secondary terminals when held a short distance apart, but the shock experienced by touching the ends was not serious. The above arrangement, with the addition of two Geissler tubes placed in series between the outer coatings of the jars, was used to illustrate the fact that closing the secondary diminishes the impedance of the primary circuit of a transformer. Experiments on condensers made of tin foil on glass were shown. In one of them, parts of the coatings in the form of letters had been removed, and the spaces became luminous when the condenser was connected with an induction coil. In another experiment a glass plate was moved to and from a condenser, and a musical note could be heard whose pitch increased as the distance between the glass plates diminished. The note was said to be the octave of an open organ pipe, whose length was equal to the distance between the plates. Mr. Swinburne thought some of the effects shown were not Hertzian, but merely cases of ordinary mutual induction. He inquired whether the vacuum tubes would still glow if the Leyden jars were removed from the so-called resonating circuits. He was also of opinion that in the magnetic experiments the surfaces of the bulbs, and not the enclosed gases, took the charges. Mr. Watson asked if the authors had tried screening off the long waves by a wet cloth. If the effects still existed, this would prove that they were Hertzian. Mr. Blakesley wished to know if the images of the rotating tubes were at equal angular distances. Mr. Smith pointed out that these distances were not equal, but corresponded to equal changes of potential. Prof. Ayrton remarked that the only cases where the materials of the bulbs, tubes, &c., did not influence the results were those in which discharges were produced by varying magnetic fields. Mr. E. T. Carter thought an induction coil a more efficient machine for producing the glow in tubes than the alternator, &c., used by Mr. Tesla. Mr. Trotter asked if the authors had observed whether the glow produced by passing a discharge through a wire wound in a long pitch spiral round a tube formed an open or a closed circuit of light. Prof. S. P. Thompson said he first noticed that sparks passed between pieces of metal in the vicinity of an induction coil sparking into a condenser in 1876, when he was showing some experiments on telegraphic apparatus before the society, but unfortunately he did not pursue the subject. Long before Mr. Tesla's investigations Dr. Bottomley had shown that exhausted tubes could be caused to glow, but it was not until Tesla produced such phenomena on a large scale that people recognized how much light could be got in that way. Mr. Rimington, in replying to a question by Prof. Thompson, said the notes heard when the glass plate approached the condenser were of very high pitch. The explanation why in the experiments performed in varying magnetic fields, the bright parts of the luminous discharges were near the wire, appeared to be that the E.M.F. was greatest in these places. Although he had not tried the experiment, suggested by Mr. Swinburne, of taking off the Leyden jar, he felt sure that doing so would stop the glow.

Geological Society, November 23.—W. H. Hadfield, F.R.S., President, in the chair.—The following communications were read:—Outline of the geological features of Arabia Petraea and Palestine, by Prof. Edward Hull, F.R.S. The region may be considered as physically divisible into five sec-

tions, viz. (1) The mountainous part of the Sinaitic Peninsula; (2) the table-land of Badiet-el-Tih and Central Palestine; (3) the Jordan-Arabah valley; (4) the table-land of Edom, Moab, and the volcanic district of Jaulán and Haurán, and (5) the maritime plain bordering the Mediterranean. The most ancient rocks (of Archæan age) are found in the southern portion of the region, they consist of gneissose and schistose masses penetrated by numerous intrusive igneous rocks. They were succeeded by the lower carboniferous beds of the Sinaitic peninsula and Moabite table-land, consisting of bluish limestone with fossils, which have their counterparts chiefly in the carboniferous limestone of Belgium, and of a purple and reddish sandstone (called by the author "the desert sandstone," to distinguish it from the Nubian sandstone of Cretaceous age), lying below the limestone. The Nubian sandstone, separated from the carboniferous by an enormous hiatus in the succession of the formations, is probably of Neocomian or Cenomanian age, and is succeeded by white and grey marls, and limestones with flint, with fossils of Turonian and Senonian ages. The Middle Eocene (Nummulitic limestone) beds appear to follow on those of Cretaceous age without a discordance, but there is a real hiatus, notwithstanding the apparent conformity, as shown by the complete change of fauna. In Philistia a calcareous sandstone in which no fossils have been observed is referred to the Upper Eocene, for the Miocene period was a continental one, when faulting and flexuring was taking place, and the main physical features were developed—e.g. the formation of the Jordan-Arabah depression is referable to this period. In Pliocene times a general depression of land took place to about 200-300 feet below the present sea-level, and littoral deposits were formed on the coasts and in the valleys. To this period belong the higher terraces of the Jordan-Arabah valley. The Pliocene deposits consist of shelly gravels. Later terraces were formed at the epoch of the glaciation of the Lebanon mountains, when the rainfall was excessive in Palestine and Arabia. The volcanoes of the Jaulán, Haurán, and Arabian desert are considered to have been in active operation during the Miocene, Pliocene, and Pluvial periods, but the date of their final extinction has not been satisfactorily determined. After the reading of this paper the president remarked on the interest of the geology of an area, which was that of the Bible. Many authors had recorded their observations on this district, one of the latest being the author of this paper. Some years ago Mr. Holland had read a paper before the Society, and he (the speaker) believed that that writer was actually the first to prove the existence of carboniferous fossils in the Sinaitic peninsula. He remarked that *Lepidodendron mosarum*, described by Salter, was somewhere preserved in the Society's museum, so that the Society had long ago had evidence of carboniferous rocks. Mr. Bauerman's paper, which was a reconnaissance in a comparatively unknown district, created great interest, and when that paper was read doubt was expressed as to whether the fossils then exhibited were carboniferous or triassic. After the researches of Prof. Hull there was no doubt that carboniferous rocks do occur in the region. As regards the granitic rocks (extending far up the Nile valley, in the Sinaitic peninsula, and elsewhere), they were all of much the same character, and, according to Sir William Dawson, occurred at two horizons—the lower rocks being granitoid and gneissic, the upper more or less volcanic, but still pre-carboniferous. He asked the author whether the Poudingues de Jebel Haroun of Lartet were or were not ancient volcanic rocks. The Nubian sandstones of older writers included many things, but the age of the various sandstones was now satisfactorily determined by the author. Some were carboniferous, others (in the speaker's opinion) cenomanian. The calcareous formations of Judæa were well known from the writings of Lartet, Fraas, and others, but the exact line of demarcation between the Nummulitic limestone and the true Cretaceous had never been determined. It was a curious fact, as stated by Von Zittel, that not one fossil was common to the two deposits, which were nevertheless quite conformable. Miocene beds appeared to be absent, for, as noted by Lartet and confirmed by the author, this was a period of movement, when the great valley and the great fault were initiated. He (the speaker) felt that there were many difficulties connected with the depression which had not yet been cleared up. Lartet, Hitchcock, and others had traced the general direction of the fault; but the author had determined its exact site at more than one point. The most interesting point in this connection was the question of the age of the 700-foot saddle separating the Akabah watershed from the Jordan-Arabah depression. This

THURSDAY, DECEMBER 22, 1892

## MR C. DIXON ON BIRD-MIGRATION.

*The Migration of Birds. an Attempt to reduce Avian Season-Flight to Law* By Charles Dixon (London Chapman and Hall, 1892)

**A**MONG prevalent fallacies there are few more mischievous than that which holds a man to be an authority on a subject because he has written a book about it. If the subject be one concerning which the scientific hold divers opinions, or even hesitate to deliver an opinion at all, so much is to the good of such an author, for he will be able to pose all the more securely in the character of a *savant*—though after all that only signifies a “knowing one.” If the author can boast of some two, three, or even half-a-dozen works already published, the fallacy becomes almost insuperable, notwithstanding that in zoological works of a popular nature, it is scarcely too hard to say that those who write the most know the least. Nevertheless it remains the duty of the conscientious reviewer to be instant in season with his protest against this general confounding of author with authority. We have read several of Mr Charles Dixon’s works, but hitherto we have been so fortunate that we have been able to keep *in petto* the judgment we have formed of them. It is not given, however, even to reviewers to struggle against fate, and it has been ordained that we should have to criticize his recent volume, the title of which may be read above. To the first sentence of his preface—“There is no branch of Ornithology more popular than that which treats of the Migration of Birds”—we offer no strong objection, and rejoice that there is one spot of ground, be it never so small, that we may occupy in common, but (woe it is!) that here we must part company, for the very next sentence contains a statement which we would willingly let pass as a harmless exaggeration, were it not intensified by the words which follow—and “after that, the dark!”

Mr. Dixon’s acquaintance with the subject he has selected is shown by the beginning of his second paragraph—“Notwithstanding the immense popularity and importance of Migration, strange as it may seem, no work has hitherto been devoted expressly to its discussion.” He is therefore not aware of the essays of Schlegel and of Marcel de Serres, which (whatever we may now think of them) were in their time “crowned” by the scientific society that published them, and though he straightway proceeds to name the works of Professor Palmén and Herr Gätke, it is to complain of them that they “have only dwelt upon a portion of the subject.” Far be it from us to say that Mr. Dixon has not read their works, but really there is nothing to show that his knowledge of them is more than may be picked up from the extracts which have been translated into English and published in this country, or that he has read them to any purpose—that of Herr Gätke especially, because, when further on (pp. 181-186) he comes to deal with it more particularly, he regards it as if it were a “mere record of captures or reputed captures of birds in Hell-goland, speaking of it with contempt, and the original and rather peculiar views on migration of its author are passed

over in silence, as though they were utterly unknown to him. Mr. Dixon states that he is “equally cognizant of the researches of Weissemann” (*sic*) and others, which, except that Dr Weissemann, we think, would deny his having made any, we do not take upon ourselves to gainsay, though our older writers are utterly ignored, and we have a shrewd suspicion that the anonymous author of the “Disco urse on the Emigration of British Birds,” published at Salisbury more than one hundred years ago, was, from actual observation, more familiar with the main facts than Mr Dixon is—all flourishes about “avian fly-lines” and “season-flight” notwithstanding—and therefore would have been more competent than he “to bring our knowledge of Migration within the limits of order or to reduce it to Law.”

Now this is exactly what in our opinion Mr Dixon has not done. What the “Law of Migration,” of which we read he and on the title-page, may be it passes us to discover. The phrase is full of sweetness, but its elucidation, if we may say so, fails in light. So also is that about bringing our knowledge “within the limits of order,” though that may be here taken to mean a dissertation within the limits of 300 pages or thereabouts containing something on the origin and descent of birds, a good deal about the precession of the equinoxes and the eccentricity of the earth’s orbit, but still more about glacial epochs. Concerning the “Law of Migration” it is pointless. Let our author at once speak for himself in what seems to be a sort of summary of his faith, though it is long and not reserved to the end of his volume—

“We will now conclude by following in detail the migration of some single species, say from its Post Pliocene glacial initiation to the present day, in order clearly to demonstrate Why the habit [of migration] has been acquired, and How it is practised.”

“We will select the Spotted Flycatcher (*Muscicapa grisola*) for the purpose. It is one of our best known summer migrants, and one whose present geographical distribution admirably illustrates the phenomenon of Migration. When the Sub Polar regions of the northern hemisphere last enjoyed a warm, almost semi-tropical climate—one of the mild periods of the Glacial Epoch—the Spotted Flycatcher inhabited in one unbroken area the Arctic woodlands from the Atlantic to the Pacific. Probably it was a resident species becoming partially nocturnal during the Polar night, food was abundant, its conditions of life were easy, and it multiplied apace, and became a dominant, firmly established species during the thousands of years that it dwelt in this Sub-Polar habitat. So matters continued until the slow precession of the equinoxes, in conjunction with increasing eccentricity of the earth’s orbit, began to have a marked influence on the climate, and gradually the fair forests and the verdant plains were devastated by the ever-increasing cold. Age after age the Spotted Flycatcher was driven slowly south; summer after summer grew colder and shorter, the periods of Polar darkness more severe. At last matters became so serious that the birds began to leave their northern haunts in autumn, probably because their food became scarce as the various insects either retreated south or began to hibernate. Further and further southward these annual journeys had to be taken, until the Flycatcher at last found its way during winter into Africa, Persia, Arabia, India, China, and even the Philippines and the Moluccas. Summer after summer the belt of breeding-ground became wider and wider, and vast numbers of individuals became separated from

the rest of the species by the lofty mountain ranges, the deserts, and other physical barriers, which would effectually assist a forest or woodland haunting species. More and more severe became the winters, longer and longer, the glaciers descended lower and lower, exterminating or driving before them all living things. At last the Spotted Flycatcher, or the form which then represented this species, came to be divided into two enormous colonies—an African one and a Chinese one—the individuals of each being completely isolated from each other, summer and winter alike. During the ages that this state of things continued, the Flycatchers became segregated into two species, owing primarily to the absence of any intermarriage, the eastern race became smaller, the tail shorter, and the breast-streaks broader, or the western race became larger, with a longer tail and narrow breast-streaks. It is almost impossible to say which form now most closely resembles the ancestral species, but such are the present differences between the two races known to ornithologists respectively as *Muscicapa grisola* (the Western and British form) and *Muscicapa griseisticta* (the Eastern form). Such was the state of things at the close of this Inter-Glacial Period.

"Then came the gradual immigration north again, as precession and lower eccentricity initiated a milder climate. Age after age the journey in the spring became longer. Certain routes to and fro came to be recognized highways of passage, and so imperceptibly did the northern breeding grounds expand that the birds became regular migrants, looking upon the movement north to higher and cooler latitudes each spring as an undertaking never to be missed. Warmer and warmer became the southern haunts, stimulating and widening migration flight to the cooler temperatures prevailing near the edges of the retreating glaciers, where a suitable breeding climate could only be found.

"Let us confine our attention solely to the birds that bred in the British Islands. In the Præ-Glacial ages this area formed part of Continental Europe, a rich and fertile corner, abounding in insect life, full of haunts the Flycatcher loved. After the banishment of its race and the exile of its ancestors in Africa, the northern journey at first did not extend further than the edges of the glaciers on the Mediterranean coasts of Europe. But as these disappeared, and a warmer climate began to prevail in higher latitudes, the annual summer flight was increased. Every century the northern breeding range had increased, creeping slowly across France, higher and higher with the growing vegetation, nearer and nearer to the haunts of old. During the slow, gradual elevation and submergence that isolated Albion from the rest of Europe during Post-Glacial time, the regular spring journey across the sea became wider and wider, but with the intense and inherited love of home in their tiny breasts, the individuals that were born and bred in this district never failed to return each year. For 60,000 years or more has this species now crossed the sea, returning every season, not only to our islands, but each pair of individuals, as long as they live, come back to the exact locality of their previous nests. This long journey, gradually growing longer and longer during thousands of years, until it is now at least a thousand miles in length, has grown to be a deeply rooted custom sanctioned by the practice of ages of experience and need, and looked upon now as part of the Flycatcher's very existence!" (pp 58 62)

This, we think, is Mr. Dixon at his best, and we are anxious that our readers should so see him. He goes on to call it a "thoroughly demonstrable instance," which shows what his idea of a demonstration is. We do not deny that all may have happened as he here prescribes,

NO. 1208. VOL. 47.]

but who knows that it did? To begin with, we may ask what proof is there of the existence on the earth itself of *Muscicapa grisola* "when the Sub-Polar regions of the northern hemisphere last enjoyed a warm, almost semi-tropical climate"? That its ancestors then lived we do not doubt, but who can tell us what they were like? What is meant by its "becoming partially nocturnal during the Polar night"? If so its eyes must since have undergone a considerable change, and that would hardly be unattended by a corresponding change in other parts of the bird's structure. But still it is a pleasing suggestion that "its conditions were easy" in those millenniums, and we hope Mr. Dixon may be right, though for our own part we cannot help fearing that the struggle for existence must have already begun. Certainly it set in at last, and those terrible glaciers drove the poor bird before them, with the effect—Mr. Dixon, we think, is to blame for not giving us the geographical details (which of course must be known to him) of the process—of dividing the species or the form which represented it, and may be presumed (though this is not mentioned) to have by that time got rid of its owls' eyes, "into two enormous colonies—an African one and a Chinese one." These were so isolated that inter-marriage between the individuals of the two portions was impossible, the remarkable consequence of which was that "the Eastern race became smaller" than the Western—a character distinctive indeed of the human races, the Pygmies excepted, now inhabiting the same lands—but with "the tail shorter"—a contradictory character, since the long tail of a Celestial is the really important part of him. We are also told that "it is almost impossible to say which form now most closely resembles the ancestral species," an unexpected confession of ignorance (the "almost" is good) after so much information, but one to which we see the necessity of bowing. However, what is the upshot of all this? And how is any "law" illustrated by it? Setting aside the vagaries on which we have just commented, it reads to us as being merely an amplification of suggestions that were tentatively and cautiously submitted in these columns more than eighteen years ago (*NATURE*, vol. x pp 416 and 459). The partiality of birds for their old homes was then, and (so far as we know) for the first time, pointed out as one possible factor in establishing migratory habit, and, as another (and equally for the first time), the growing divergence of breeding and feeding areas through climatic causes was briefly and clearly set forth by Mr. Wallace. Notwithstanding Mr. Dixon's assertions, he does not seem to have advanced the question one bit, but he has overwhelmed it in a flow of words with a great deal that is, and apparently always will be, incapable of proof. Here and elsewhere throughout this volume we are brought to face one of that school of biologists, the growth of later years, which may be called the Assertive. In some respects it is a very nice one to join. You have only got to say what first comes into your head, and all goes well. Everybody that differs from you is a fool. To some extent this school resembles that Dogmatic one which a few naturalists here and there still remember, inasmuch as the dissentient from either was regarded with the same contempt. The Dogmatists have had their day, but if we look back upon their doings, we shall see that in most cases they had something to go upon which

was not entirely assertion. They were very fond of facts, and undoubtedly preferred founding their dogmatism upon them—indeed, nothing could be more distasteful than to suppose each dogma had not a sound basis. In most cases the worst of which they can even now be accused is that the facts were often above their comprehension, or were understood in the wrong sense. But these men would have scorned the grounding of their dogmas upon imagination. They were perfectly aware (only it had not then been so neatly put) that "Imagination is the fire of Discovery—the best of servants though the worst of masters." Now the Assertive school, of which in this country Mr Dixon, if he was not the joint-inventor, may be looked upon as a chief leader, rests nearly all on imagination. It matters little whether there is reason behind their assertions or not, and generally, we regret to say, there is none. Conjectures follow upon conjectures and are put forward for the most part as if they were serious deductions from observation. It is not so many weeks since some words, that seem very applicable here were addressed to a scientific audience—

"We have had enough of the untrained writer of papers, the jerry-builder of unfounded hypotheses whose ruins cumber our field of work."<sup>1</sup>

Mr Dixon, with his long string of previous books, may demur to being termed a writer of this kind, but he certainly needs to be taught the meaning of the word "probable" and its derivatives. When he has learned it perhaps he will use it in its fit sense. With him, at present, it is in many cases to be rendered "possible," while in not a few *impossible* would be the true equivalent. Now according to all etymologists, and the harmless drudges known as dictionary makers, "probable" signifies *something that can be proved*. Any reader of average intellect will be able to calculate how seldom this unhappy word is correctly used by Mr Dixon. It has long been a custom in certain fevers to affix an ice-cap on the patient's head whereby the burning brow is cooled, and some temporary relief afforded, but of late years, as pretty well all know, there has sprung up a small group of writers to whom ice on the brain, instead of being a soothing remedy, is a direct incentive to acts and dicta bordering upon lunacy. On behalf of the Glacial Epoch, the Post-Pliocene Glacial Epoch, to be very particular, we must protest against its being constantly paraded as the greatest event in the history of the globe, to which in its momentous effects all others must give place. That it produced considerable changes and especially in the geographical distribution of plants and animals none can doubt, but that it is accountable for all that Mr Dixon lays to its charge is hardly likely, and is most decidedly not "probable," since means of proof are wanting. But

Mr Dixon, with others of the Assertive school, is not consistent in his statements, and is apt to forget on one page what he has written on a preceding one. For instance, we are told (p. 33) that "From the commencement of this Glacial Epoch, the Migration of birds, as we see it at the present time, was probably initiated," and yet, only a few lines further on, our author declares "that we do not require even the occurrence of one Glacial Epoch to account for the Migration of birds," and (p. 34) that "such a cause

amply sufficient in every respect is to be found in the varying places of Earth's [*sic*] orbital eccentricity in combination with the precession of the equinoxes"—this statement being immediately followed by a passage, the application, or even the meaning, of which is not easy to understand—

"That these majestic phenomena are in any conceivable way connected with the migratory movements of birds seems utterly impossible, but in them the habit has its root, and the simple season-flight of a Cuckoo or a Nightingale to and fro between the shores of Africa and England is inseparably and directly connected with the erratic movement of a planet in its orbit, nay, with the constitution of a universe!"

This note of admiration is our author's own—far be it from us to impair its influence.

Though we have confined our remarks to the earlier part of Mr Dixon's book, we have already devoted a good deal of space to him. There is, however, another point on which we must say a few words. He has thrown out a direct challenge to NATURE, and we should be sorry not to meet it. That he believes in migration the whole volume shows, but there is yet left in his mind a cranny wherein lurks what we may perhaps call a "pious opinion" in favour of torpidity—as a luxury in which a lazy bird may occasionally indulge, even though that bird may be one possessing powers of flight far beyond the average. He is very severe on an anonymous reviewer in these columns in that the "Theory," we use Mr Dixon's word, of Torpidity "was subjected by him to the bitterest ridicule and denounced as folly." Thereupon he favours us (pp. 12, 13) with another version (substantially, let us say at once, the same as the original, but with fewer details) of the story told by the Duke of Argyll in these pages (NATURE, vol. xv pp. 527, 528) to say nothing of some other observations, quite irrelevant, as it seems to us, communicated by his Grace to him. But further than this, he cites as an additional witness in defence of the impeached "Theory," Dr Elliott Coues, who is said to give it "all the support of his authority as an ornithologist of the highest eminence." Now we have a great respect for that gentleman, but his vast reputation fails to hypnotize us, and such support as he gave has already been the subject of comment in these pages (NATURE, vol. xx p. 2). He will hardly be comforted to learn that the supposition there made has been amply confirmed of late by Mr Hartert, who informs us (*Cat. B. Brit. Mus.* vol. xvi p. 481) that the British Museum contains five specimens of *Chatura pelagica* from Central America, beside the one before noticed from Mexico—proving that its range is much about what might have been expected. Thus all the argument based on Dr. Coues's statement, that this species was "not known to winter anywhere out of the United States, nor is it found anywhere in them at that season," falls to the ground, as we are sure that gentleman will readily admit. We allow that it has been very naughty of naturalists if they did prepare this pitfall for Mr Dixon, but that is not our business, and we cannot imagine they did it intentionally. It is not unlikely that the Chimney-Swift flew out of shot, or too fast for them to bring it down, but they have at last succeeded in "grassing" their bird, with a result so disastrous to the "Theory." One chance

<sup>1</sup> British Association for the Advancement of Science. Edinburgh, 1892. Address of the President of Section H (NATURE, vol. xvi p. 399).

yet remains for our author, for though "unfortunately no direct evidence of torpidity has ever come under" his own observation, the *Dundee Advertiser* of April, 1884, supplies him with another straw at which to grasp—not that the newspaper-writer saw it at all in that light, for he called the bird in question a "wanderer," which term is innocently repeated by Mr Dixon, apparently unconscious that thereby he gives up his case, and down he must unless some one throws him a life-belt. Meanwhile that of the "hibernating" bird is as desperate. Deprived by the brutal sceptic of its ancient refuge in the depths of Lapland lakes, or in the crumbling banks of Persian rivers, in the mud walls of Orkney or in Irish dung-heaps, or even in nests of its own building in sea-girt Schleswig-Holstein, the *fin de siècle* Swallow desirous of enjoying torpidity has to betake itself to the security of the Bell Rock Lighthouse, and even there to excite no particular astonishment on the part of the honest men who welcomed it. If they had looked upon it as the spirit of Robert Stevenson, or that Abbot of Aberbrothock whose memory was blessed by mediæval mariners, there would have been some excuse for them, but they simply regarded this Swallow as the proverbial one that doesn't make a summer—it was the 12th of March. They will, we think, learn with surprise from Mr Dixon that "this bird may probably have spent the winter, dormant, near the lighthouse," while he considers "that we here have the most trustworthy evidence of a positive kind." If this does not indicate hibernation capabilities amongst certain birds, pray to what else can it be attributed?" (p. 16). We leave our readers to answer this question as they please, but we fear their answer will not please him. They may, however, like to know how the incident was recorded in the Migration Committee's schedule by the matter-of-fact observer—"1884, March 12th. One Swallow (Swift) 4 p.m. [Wind] S E, strong B[reeze] [Weather] cloudy Arrived much exhausted." No more and no less.

Returning to the position whence we started we must express our deliberate conclusion that Mr Dixon, author of so many works as he may be, is no authority on the subject of Migration, which he has left exactly as he found it. In the hope he entertains that his volume may form "a basis for more elaborate study and detailed research" we entirely concur. On one, and that the most wonderful part of the whole business, the faculty whereby birds are enabled to perform their extended flights with such punctuality and general unerringness that the more one knows of the subject the more one is amazed at it, he is silent, for it would seem that there are even bounds to his imagination, and for this we are thankful.

### DOMESTIC ELECTRIC LIGHTING

*Domestic Electric Lighting, Treated from the Consumer's Point of View.* By E. C. De Segundo, Assoc. M. Inst. C.E. (London: H. Alabaster, Gatehouse, and Co., 1892.)

THE author of this small volume is of opinion that there is at present no literature obtainable to enable the untechnical public to form a judgment as to the suitability of applying electrical energy to meet their various requirements, and he states that at present the extended applications of electricity are largely engrossing attention,

but owing to the conflicting views expressed by those ignorant or interested, there is a probability of a feeling of disgust being engendered for all things electrical in the lay mind. No doubt there is a good deal of truth in this statement, on the other hand, those who take any interest in this all-important subject will soon learn enough to be able to discern that which is important and worth knowing. The volume under notice has been written in order to fill this want in electrical literature, and to teach the consumer of electrical energy something of the source of the light and power he is using.

It is admittedly a difficult task to make a technical subject clear to untechnical, though interested, readers, and in this case all the more so, on account of the extreme technicalities of electricity as applied to everyday requirements.

The author begins at the very beginning, and in Chapters I and II deals with the lighting of rooms with gas, oil, and electricity, naturally pointing out how very soon the atmosphere is vitiated by the two former illuminants, besides the damage done to paintings, book-bindings, &c. When discussing "How shall I light my house best?" the author treats of the efficiency and cost of the different illuminants, and points out that although the electric light may be the more expensive, yet the cost per lamp per hour may be fairly compared with oil or gas, because these illuminants are seldom turned completely out when a room is temporarily empty, whereas the facility of switching on and off an electric lamp must naturally save the current and effect economy.

Chapter III consists of a short description of some of the systems on which electric light is produced and supplied. Great diversity of opinion exists as to which is the best system on which electric energy should be supplied for public use. In London two systems are in vogue, viz., The high pressure alternating current in conjunction with transformers, and the low pressure continuous current system. From the consumer's point of view, so long as the high pressure current is not allowed to enter the house, it matters little what are the conditions of distribution, provided a continuous low pressure direct supply or a low pressure alternating current from a transformer station is delivered to him, except, of course, where motors are in use, and then the continuous current is a necessity. For installations in the country, separate generating plant is required, and for small installations, where on the average fifteen lamps of 8 c.p. are in circuit at a time, the author says that the electrical energy can be economically generated by chemical means. The primary battery referred to is a modified form of Bunsen, and the cost of producing the light is stated to be one penny per lamp of 8 c.p. per hour. No doubt such a battery takes the place of engine, dynamo, and accumulators, but it is purely a matter of opinion as to the trouble and skill required to look after these batteries, and, without taking the prime cost into account, a gas or oil engine driving a dynamo and charging accumulators to run these fifteen 8 c.p. lamps should not cost fifteen pence per hour. A case is known where an Otto domestic gas engine is easily driving seven and sometimes eight 8 c.p. lamps, and consuming 24 cubic feet of gas per hour, at a cost of considerably under one penny per lamp, the lamps being run direct off the dynamo.

The progress of private electric lighting is simply astonishing, the gas engine being generally the motor used. Many of these engines are run by the Dowson gas, made on the spot, thus rendering a supply of illuminating gas unnecessary.

The author treats somewhat in detail the cost of electric lighting in a house, but as this largely depends on the type of pendants, brackets, &c., used, the outlay naturally varies considerably. The most serious item in the maintenance of an installation is the breakage of the lamps. The author rejoices that this monopoly of manufacture will soon expire, when competition will place better lamps on the market at half the present cost.

Taken as a whole this little book is interesting and useful. It will certainly help the uninitiated consumer to study intelligently the principles of electric lighting, and render his conception of necessary expenses when installing the light more sensible.

#### OUR BOOK SHELF

*Grasses of the Pacific Slope, including Alaska and the adjacent Islands*. Part I. By Dr Geo. Vasey, Botanist, U.S. Department of Agriculture. 8vo, 56 plates, with descriptions. (Washington Government Printing Office, 1892.)

THE botanists of the United States Department of Agriculture are working very energetically, and the importance of the herbarium, library, and its publications is increasing year by year. The present work is part of a series of illustrations of the North American grasses, of which we have already noticed two parts, together making one volume, devoted to descriptions and figures of the characteristic species of the South-Western States. The present part, which will constitute half a volume, is devoted to California and the Western States. Dr Vasey tells us in his introduction that the grasses which are known to grow on the Pacific slope of the United States, including Alaska, number not far from 200 species, which is nearly twice as many as we get in the British Islands. They are all specifically distinct from the grasses growing east of the Mississippi, and also mostly distinct from the grasses of the plains and of the desert, except in that part of California which partakes of the desert flora. A considerable number of the grasses of the mountainous regions of California, Oregon, and Washington reappear in the mountains of Idaho, Montana, and the interior Rockies. The interior of California is a dry region, verging in the extreme south into the desert country, and is deficient in grasses, especially of those species which form a continuous turf. In the present publication fifty of the most interesting species are described and illustrated.

The descriptions are almost wholly the work of Dr Vasey's assistant, Prof L. H. Dewey. The illustrations are excellent, and are the work of various artists—F. Muller, W. R. Scholl, T. Holm, and others, and are accompanied by full dissections. The species range under the genera as follows—*Imperata*, 1; *Panicum*, 1; *Cenchrus*, 1; *Phalaris*, 2; *Hierochloa*, 1; *Aristida*, 1; *Spiza*, 9; *Oryzopsis*, 2; *Muhlenbergia*, 5; *Alopecurus*, 7; *Agrostis*, 6; *Calamagrostis*, 10; *Deschampsia*, 1; *Trisetum*, 3; *Orcuttia*, 2. Only two out of the fifty species are British, *Alopecurus geniculatus* and *Deschampsia cespitosa*. J. G. B.

*Aids to Experimental Science*. By Andrew Gray (Auckland: Upton and Co., 1892.)

THE chief interest of this little book lies in the fact that it gives a glimpse of the science teaching in one of our

colonies. It is a compilation of simple experiments in mechanics, physics, chemistry, physiology and health, and agriculture, to prepare students for what is known as the Class D examination. Naturally, most of the experiments are old ones, but here and there one may gather a new idea. The portion dealing with physiology and health has nothing to do with dissection, but consists of experiments on ventilation, drainage, food stuffs, and the like. An interesting piece of apparatus, devised by Prof Bickerton for showing the action of the lungs, is described on p. 76. All the experiments are briefly but sufficiently described, and many of them are illustrated.

*Science in Arcady*. By Grant Allen (London: Lawrence and Bullen, 1892.)

THIS volume will fully maintain Mr Grant Allen's reputation as a popular writer on science. The essays of which it consists are written in a bright, lively style, and may be read with pleasure even by original investigators, for the truths with which they deal, if not new, are at least presented from new points of view. Readers who do not profess to know much about any particular branch of science will find in these papers an excellent introduction to some of the more attractive facts and laws of the natural world. The volume includes some archaeological essays, which show very effectually that an antiquary has not necessarily much resemblance to Dr Dryasdust.

#### LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### Macculloch's Geological Map of Scotland

IN a recent article in this journal Prof. A. H. Green writes as follows—

"Macculloch seems to have projected, but never completed, a geological map of the whole of Scotland. The materials collected by him were, however, utilized by the Highland Society in the construction of a general map in 1832."

I am sure that nothing could be farther from the wish of the Oxford Professor than to do an injustice to the memory of one of the greatest of the pioneers in British geology, and he will therefore forgive my calling attention to the following facts, which, judging from a subsequent letter in these pages, would seem not to be generally known.

During the last twenty years of his life Dr John Macculloch was engaged on a regular survey of Scotland, and in collecting the materials for a geological map of the country. In the earlier part of this period Macculloch seems to have availed himself of the opportunities afforded to him as an official of the Board of Ordnance to carry on his valuable geological explorations. But during the latter part of the period he was regularly employed by Government to complete his geological work, and was paid by the Lords of the Treasury, who in the end published his map.

On July 28, 1834, Macculloch addressed to "His Majesty's Treasury" a series of memoirs respecting the Geological Map of Scotland, which was then completed. In these memoirs he refers to the map as being then in existence, and gives the most minute directions concerning the tints to be employed by the colourists who were to copy the map, in order that it might correspond with his original work. He also expressed his regret that the imperfect topography of the map on which his researches had to be recorded prevented the work from being as accurate as he could have wished at certain points.

Owing to delays in issuing the Government publications—not quite without parallel in more recent times—Macculloch's "Memoirs on the Geological Map of Scotland" did not appear till the year following his death (1836). The date at which the first copies of the map were issued it would probably be difficult to determine, but as to the completion of the map before July 1834,

and its subsequent issue by "the Hydrographer to the King by order of the Lords of the Treasury" there can be no doubt whatever.

The first Government Geological Survey undertaken in the British Islands was that of Dr John Macculloch, and the work that he accomplished single-handed was a very remarkable one. Several geological maps of Scotland, differing very widely from that of Dr John Macculloch, have been issued and withdrawn during the last fifty years, but any one who will compare the first geological map of Scotland with the latest, also "published with Government authority," will be interested to see how far the work of the early pioneer in Scottish geology has been found to be correct in most of its essential features by those who have come after him.

John Macculloch's title to be the author of the first geological map of Scotland is as indisputable as are the similar claims of William Smith and Richard Griffiths with respect to England and Ireland respectively.

JOHN W JUDD

16, Cumberland Road, Kew, December 6

### Glaciers of Val d'Herens

THE two glaciers of Arolla are interesting, inasmuch as one, the Arolla, is retreating, while the other, Glacier de Zigorenove, is advancing. This has been going on for twelve years, according to the report which appeared in NATURE (vol. xlii p. 386), by Dr Forel, dealing with Alpine glaciers and their changes.

Having visited these glaciers last summer with the object of observing the effect of their respective movements upon the morainic accumulations in front, I think a brief account may be worth recording.

The Arolla glacier occupies the head of the valley, and is fed by the snow from Mont Colon and the fields of neve extending towards Mont Brül. The Zigorenove glacier is one mile further down the valley, but does not descend so low as the Arolla glacier by about 300 feet. It receives its main supply from the Pigne d'Arolla, a mountain which rises immediately above the glacier, and is conspicuous by its massive snow-cap. This glacier is not only nearer to its supply, but descends at a steeper gradient than the Arolla glacier.

This may in some measure account for the former advancing while the latter is retreating, or, more correctly speaking, melting backwards. I was informed by local guides that the Arolla glacier has been swelling behind for some years, if this be correct, and the seasons remain normal, then, in a short time, this glacier must advance also, in other words, being longer or further away from its feeding ground, the extra supply has not yet had time to reach its extremity. Appearances at the end of the glaciers are in themselves quite sufficient to indicate their respective movements, the snout of the Arolla glacier is buried in its own debris, composed of rocks and loam borne upon or concentrated to the surface as the ice melts. This debris is being constantly shot down grooves or water courses furrowed in the sloping end or side of the glacier. At the bottom of these spout-like grooves conical shaped mounds are formed, one behind another, as the ice melts backwards, resulting in a moundy, zigzag arrangement constantly seen lower down the valley, many miles away from existing glaciers, and can be seen also in many of the higher valleys of North Wales.

The advancing Zigorenove glacier, instead of being buried in debris, turns up in shell-like flanges, exposing its under surface in its endeavour to climb over, rather than push forward, the loose rocks in front, a part of this loose material only is pushed forward, forming a small bank, which in no place exceeded 5 feet in height, up which the ice mounts with the shell-like flanges projecting beyond, the under part of these projections being fluted into a perfectly symmetrical pattern.

In some way the projecting rocks forming the glacier bed produced these convolutions, but whether by cutting, melting, or by the ice crystals flowing round each side, I was unable to determine, but I may state there was no appearance of cutting or grinding which would necessarily leave behind the shavings or ice particles cut out or ground off, and little or no water was present as if from melting. We had much snow for three days, with a total absence of sunshine, the atmosphere at mid-day, when making these observations, registered 38° F. Appearances rather suggested the idea that the ice crystals were displaced in a similar manner to water in a rapid river when it meets with obstructing boulders in its bed.

Climbing up one of the old lateral moraines, for there are several, the glacier is seen to be encroaching laterally as well as longitudinally, it soon extends to the base of the inner moraine, and then climbs upwards in a similar manner as it advances in front by turning up its edges, carrying upwards a few loose rocks in front, but without materially disturbing the moraine itself. Higher up it reaches the top of this moraine, and then rises above it like a wall, having caused the loose rocks it had borne up to roll down into the valley between the inner and outer moraine, with masses of ice broken off the edge of the glacier.

As far as I am able to ascertain, by creeping under the flanges the glacier slowly spreads out the bank which it had pushed up in front as it advances into a more even bed to travel over, but my observations were restricted to a few yards owing to the contraction of the sub-glacial space between the ice roof and the floor. I was much impressed by the fact that the glacier did little in exerting that force which might be expected from such a power behind, in the way of ploughing through or removing such comparatively trifling obstructions as loose rocks or moraine banks.

It is evident from the various ages of moraines that the lower parts of those glaciers have fluctuated considerably during recent times, but the line of demarcation between these minor fluctuations and the period after these lateral valley glaciers had been confluent with the main Valais glacier, and were retreating backwards, is very marked. Beyond two miles down the valley from the Zigorenove glacier no stripe from the trunk glacier could be found, but at this distance it suddenly appears with fresh glaciated forms, precisely the same phenomenon was noticed in the neighbouring Val d'Anniviers, as if this were the limit of the more recent fluctuations.

At the Col de Bertol, 4500 feet above Arolla, or about 11,000 feet above sea level, there are no indications of glaciation, ancient or modern, above the surface of the snow; so it would appear, however much the ice level has varied below, at this dividing ridge it has always remained the same, or, in other words, it has been dispersed by wind or ice movements to lower levels at a rate equal to deposition, when the snow line was low enough to allow the ice to travel down the Val d'Herens, the higher ice streams would simply run down upon its surface, instead of descending as low level glaciers or mountain rivers, as at present.

WILLIAM SHERWOOD

Eastbourne House, Sutton Coldfield

### Ancient Ice Ages

MESSRS BLANFORD, in their letter (NATURE, p. 101) called forth by Dr Wallace's notice of a palæozoic glacial conglomerate in Victoria, Australia, say—"It has become an accepted article of faith amongst most European geologists that no ice-age occurred before the last glacial epoch." There is no doubt that the tendency of opinion has been in that direction, notwithstanding the evidences to the contrary brought forward by Dr. Blanford and others. The late Sir Andrew Ramsay was the first, so far back as 1855, to suggest that the Permian conglomerate of Abberley and the Clent hills was an ancient glacial deposit. Although this reading was accepted by an cautious a philosopher and critic as Sir Chas. Lyell ("Principles," 10th ed., vol. i p. 223), the idea has languished from disfavour. Having devoted a considerable portion of the last twenty years to the study of glacial phenomena, I early this year paid my first visit to the district. The best section I saw is an excavation at Abberley in what may be called boulder gravels, and, except for its prevailing red colour, the deposit, if dropped down on the coast of Wales, would, in general appearance and arrangement of the materials, be undistinguishable from many of the glacial deposits to be found there. Many of the stones have flattened faces, and in general shape resemble glaciated boulders, but the striae, so far as I could observe in the limited time at my disposal, were not very pronounced. Since then I have found a deposit of glaciated gravels on the top of the Screes, Cumberland, 1600 feet above the sea, which on comparison with the specimens brought home from Abberley enables me to understand the latter better. The volcanic rocks of the lake district of which these gravels are composed break up into very similar shapes, and are planed and striated in a very similar way to those of Abberley. I also brought home from Abberley two specimens of the "paste" which fills up the interstices of the finer gravel.

On washing and riddling this clayey matter, well waterworn and smooth gravel was separated from it up to about the size of a bean, and on many of these minute pebbles, with the aid of a microscope of low power, beautifully developed striae are to be seen, sometimes on more than one face. This latter fact appears to have been unnoticed before. The conclusion I have come to is that Ramsay had reasonable grounds for his belief in this being a Permian glacial deposit, and think that if he had given more details in his otherwise able paper, geologists would probably have followed him more freely.

### The Earth's Age

As Dr A. R. Wallace's "Island Life" may be regarded as one of the best authorities on its subject, it appears desirable that any errors in it should be pointed out, lest any of its numerous readers should be misled.

In Chapter X (2nd edition, 1892) is an estimate of the earth's age based on the following data—Land area of globe, 57,000,000 square miles, coast line, 100,000 miles, width of shore deposits, 30 miles, hence area of shore deposits, 3,000,000 square miles, hence rate of deposition 19 times as fast as that of mean rate of denudation, which latter is taken to be 1 foot in 3000 years.

Thickness of stratified rocks 177,200 feet, hence time required for deposit 28,000,000 years. This last result is taken to be approximately the earth's age.

It appears to me that Dr Wallace's data warrant no such conclusion, for, in the 28,000,000 years in question, all that would have been deposited would be a thickness of 177,200 feet of rock, over an area of only 3,000,000 square miles, whereas, what has to be accounted for is an area of 57,000,000 square miles (neglecting igneous rocks and sedimentary deposits beneath existing sea) of the same thickness. Therefore, so far from Dr Wallace's data leading to 28,000,000 years as the earth's age, they actually lead to a result 19 times as great, viz 532,000,000 years.

Sir A. Geikie's estimate is (NATURE, vol. xlii, p. 322), 100 to 680 million years. Personally, I think, the method of taking maximum thicknesses of deposits unsatisfactory, for it assumes that every formation was deposited, with its maximum thickness, over the whole land area of the globe. The absurdity of this supposition is obvious. The only defence of it is that it is held to make an ample allowance (of unknown amount) for repeated denudation. It would, perhaps, be better to ascertain the actual thickness of a great series of successive formations, say in the Colorado Cañon and other regions, and from such data to estimate the total average thickness. This estimate, of course, would allow nothing for repeated denudation, but would enable one to form an idea of the earth's minimum age.

BERNARD HOBSON.

Owens College, Manchester, December 5

I AM glad that Mr Hobson has formulated his difficulty as to the measurement of geological time by the comparative rates of denudation and deposition, because it shows that I cannot have explained my views as clearly as I thought I had done, yet on again reading over pp. 217-223 of "Island Life," I can hardly understand how he has missed the essential point of the argument. Fortunately, there is no dispute as to the data, only as to the conclusions to be logically drawn from them.

Mr Hobson says that I account for a deposit of 177,200 feet (the supposed thickness of all the stratified rocks) over an area of 3,000,000 square miles (the estimated area over which at any one epoch stratified rocks are being deposited) in 28,000,000 years (the deduced estimate of known geological time), and then adds: "Whereas, what has to be accounted for is an area of 57,000,000 square miles of the same thickness" (my italics). This seems to me a most amazing misconception, for it means that every single formation and every stratum or member of each formation, was deposited to the same average thickness over the whole land surface of the globe (area 57,000,000 square miles)! And this implies that at every successive period, from the Laurentian to the Pliocene, the conditions of denudation and deposition were totally different from what they are now, since at the present time it is demonstrable that the area of deposition of continental debris is only a fraction of the whole continental area. It implies further, that

during each geological period the whole of the existing land area must have been, either at once or in rapid succession, sunk beneath the sea in order to allow of its being all covered with each successive formation—an amount of repeated upheaval and depression which hardly the most extreme convolutionist of the old school would have postulated. I cannot make the matter clearer, and trust that on further consideration Mr Hobson will admit that his objection is invalid. ALFRED R. WALLACE

### The Colours of the Alkali Metals

IN NATURE (vol. xvii, p. 55) is a communication by Mr G. S. Newth, entitled "Note on the Colours of the Alkali Metals."

I write to call attention to my article on "The Colour and Absorption-Spectra of Thin Metallic Films, and of Incandescent Vapours of the Metals," with some observations on Electrical Vitality," published in the *American Chemical Journal* (vol. xiv, p. 185) and reprinted in the *Chemical News* (vol. lxxvi, p. 163), which gives the method employed by Mr Newth, as well as other methods for obtaining metals in thin films.

In it attention is also called to the fact that the colour of the film of the metal and the colour of the vapour are widely different.

Mr Newth, however, succeeded in getting a film from sodium on glass, while I did not, and his success was probably due to the use of a higher vacuum than I employed. He also obtained a rubidium film.

In my paper I called attention to the similarity in colour of the film by transmitted light and that of the incandescent vapour which is very striking in many cases. In this respect the film of rubidium as obtained by Mr Newth follows the rule fairly well, but the film which he got from sodium is exceptional, as, according to the analogy furnished by other metals it should be yellow. The presence of potassium, however, might cause the green colour which he observed, by the combination of yellow and purple.

### Osmotic Pressure

IN an article on osmotic pressure, in NATURE (*ante*, p. 103), Mr Rodger very truly remarks that "at present the attitude of the prominent upholders of the new theory [of solutions] is one of indifference as to the exact mechanism of osmotic pressure. The numerical agreement between the measurements on solutions and those on gases is regarded as ample justification for considering dissolved substances to be in a pseudo-gaseous condition." Such an indifference is surely to be regretted from any truly scientific point of view, especially as those explanations which have been given of the mechanism of osmotic pressure have been based on the supposition that the dissolved substance is in a *veritable* and not merely *pseudo* gaseous condition. There are, however, many reasons for supposing that while the dissolved substance may for many purposes be regarded as analogous to a gas, it must in reality be in a very different condition, and that osmotic pressure is not due to the bombardment of the free molecules of the dissolved substance against a diaphragm through which they cannot pass. The impenetrability of the diaphragm to certain molecules can scarcely be attributed to any other cause than that the molecules are too large to pass through the interstices of the former, and it is scarcely conceivable that the molecules of water which do pass through can be much smaller than the molecules of simple salts, which do not pass through, still less that they can be smaller than the single atoms into which these salts are said to be dissociated.

A very simple experiment, which I mentioned some time ago in the *Ber. d. deutsch. Chem. Gesell.* (24, 3639), appears to settle definitely against the view that osmotic pressure is due to impenetrability to the dissolved substance. A solution of propyl alcohol and water was put into a porous pot and immersed in a vessel of water, the water passed through the pot to the solution, and this, according to the usual explanation, would show that the pot was impermeable to the propyl alcohol. The same solution was then immersed in a vessel containing propyl alcohol, when the alcohol was found to pass through to the solution, from which we should have to draw the diametrically opposite conclusion that the pot is impermeable to the water. The true conclusion obviously is that the pot is impermeable, neither to the alcohol alone, nor to the water alone, but to the solution of these in each other, and that the molecules composing this solu-

tion must be larger than those of either of the two substances when separate; the solution consisting of compounds or hydrates of the two. I showed, moreover, in the paper above referred to that the hydrate theory of solutions was quite capable of accounting for and explaining the fact that the dissolved substance may for many purposes be regarded as being in a quasi-gaseous condition in weak solutions, and that calculations based on the idea of its being truly gaseous would yield very nearly correct results.

The hydrate theory will also, as I showed, give an explanation of the fact that electrolytes will give abnormally high osmotic pressures, and that the magnitude of these pressures can be calculated from their electric conductivity and the explanation based on this theory also obviates many of the objections to which the idea of dissociation into ions is open. Moreover, the only critical experiment which, as far as I know, has ever been made to test the validity of the dissociation hypothesis, gives an unequivocal answer against it, and in favour of the hydrate theory. When, for instance, sulphuric acid is dissolved in excess of water, it is represented by the dissociationists as splitting up into its ions, so that the solution will contain more acting units (ions and molecules) than the acid and water together contained before they were mixed; whereas, on the hydrate theory, combination will have occurred, and there will be fewer acting units present. The number of acting units may be ascertained by observing the depression produced by the solution on some other solvent, such as acetic acid (that is, by using the very method which the dissociationists use to prove the supposed dissociation of substances), and when this is done it is found that the sulphuric acid solution contains *fewer*, instead of *more*, units than the acid and water separately.

Even if the above were the only arguments to be urged, it is evident that although the idea of the dissolved substance being gaseous and often dissociated may be a good working hypothesis for the directing of investigation, it can scarcely be accepted as a true theory of the nature of solutions.

SPENCER PICKERING

#### On a Supposed Law of Metazoan Development

It is difficult not to feel disappointed that Dr. Beard has given only "a preliminary sketch by way of clearing the ground" (*NATURE*, vol. xlvii p. 79), in place of "producing the full argument" for a law in the existence of which he has by "observation and reflection" been led to believe. For it is not easy to gather from his sketch how he is able to apply a universal law to so varied a series of events and phenomena such as he mentions, and at the same time to point out "the analogy which obtains between the suggested mode of Metazoan development, and the accepted fact of an alternation of generations in the life histories of all plants above the lowest Thallophytes." For in the higher plants the alternation of generations referred to occurs with constancy as regards period of life history, and varies only slightly within the limits of the same group.

Dr. Beard alludes, I presume, to one form of alternation of generations—that of sexual with asexual generation only, or Metagenesis. This he asserts constitutes a general law in the development of Metazoa.

In a sense this may be true enough. If, for instance, we regard the division of each cell as a new asexual generation, then Metagenesis is a very constant phenomenon amongst Metazoa. In this case the life history of a Metazoon consists of a sequence of thousands of asexually produced generations alternating with one sexually produced generation, which gives apparently a stimulus for another run of asexual generations in which polymorphism and division of labour are exhibited in extraordinary complexity and beautiful harmony.

But this is not at all what Dr. Beard means. The series of instances which Dr. Beard gives, or system of "nursing" as Steenstrup termed it, is at most a series of disconnected phenomena of frequent occurrence, and not a law.

Because most Metazoa possess eyes, it is not therefore a law of Metazoan development that eyes should be developed. Diversity in form, number, and time of appearance of eyes, is sufficient to show that the law cannot exist, so also is it in the cases of nursing to which Dr. Beard alludes, and on which he bases his argument.

It seems to me that no "law" of alternation of generations in Metazoa can be "enunciated" unless there is evidence forth-

coming of its constant action at corresponding periods in the life histories of all animals of different groups, and in a closely similar manner in individuals of one and the same group. Also a law of such a nature, if it is to be found to act universally amongst Metazoa, must surely have come into action at a very early period in the evolution of Metazoa.

Metagenesis is of constant if not universal occurrence in the cycle of life of Protozoa. A long series of generations produced asexually is followed by a generation produced sexually, that is, a generation produced by the conjugation of two individuals, this is followed again by another long series of asexually produced generations, and so on. If this is so constant among unicellular organisms of the present day, it is not very unreasonable to suppose it was common among the protozoan ancestors of the Metazoa and of the Plants. If we are to find any form of Metagenesis as a *universal phenomenon* in the Metazoa, it must be to the most protozoon-like stages of development of the Metazoon that we should look.

There is but one strict meaning to the phrase sexual generation, and that is a fusion of two cells. If Metagenesis means anything it means the alternation of a generation resulting from the fusion of two cells, with one or more generations resulting from the division of cells.

This we can perhaps find in the protozoon-like stages of Metazoan development, and in a way analogous to the alternation of generations among plants.

Spermatozoon and ovum fuse and form the fertilized ovum which is the true sexually produced generation. This produces by division a vast number of cells, and if we regard these as a number of generations then Metagenesis is obvious enough. But it is no more metazoic—if I may use such a word—to call the whole animal resulting from the segmentation of the fertilized ovum, the sexually produced generation.

This generation buds off the immature ovum. This is really the "Primitive ovum" of the embryo. I see no reason why this may not be regarded as a distinct asexually produced generation—like the formation of the spore of the plant.

The immature ovum divides into two cells—first Polar body, and more mature ovum. The more mature ovum divides into two cells, namely, second Polar body and mature ovum. It does not materially affect the argument whether we should regard these two processes as two separate consecutive asexually produced generations, or as one asexually produced multicellular generation. If we take the latter view, then the maturation of the ovum is more analogous to the prothallus stage of the life history of plants.

In either case the result is the formation of the mature ovum, comparable to the oosphere of plants.

The mature ovum fuses with the mature spermatozoon, and the sexually produced generation recurs, and the cycle of development is completed.

I cannot help thinking that if Dr. Beard wishes to discover a law of Alternation of Generations applicable to the whole of the Metazoa, he will find a more favourable hunting ground amongst those stages of development at which the several groups of Metazoa approximate, than amongst those stages where they are farthest apart, and also Dr. Beard will find the analogy between the supposed Metazoan law and the accepted law of the vegetable kingdom closer than he could ever hope to find it if he continues his present line of search.

If the above theory of the cycle of Metazoan life can be considered tenable, we see that both in the Higher Plants and in the Metazoa there are constantly alternating "sporophyte" and "gamophyte" generations, and further, we can find evidence, as we should expect to do, of the origin of such a universal phenomenon in the single celled or protozoan life, where the continuance of the species may be secured in both these ways, namely, by the formation of asexually produced spores, and as a consequence of cell fusion, i.e. conjugation.

RIC ASSHETON

#### Oxygen for Limelight

THE employment of oxygen for limelight and other purposes has increased enormously since the commercial introduction of the Brin method, by which the gas is separated from atmospheric air by a now well-known chemical process. The gas so obtained is practically pure, analysis showing that as now supplied by the Brin companies it contains on an average 95 per cent of oxygen, the remaining five per cent, consisting of inert nitrogen.

The success of this comparatively new industry has been so marked, that, as a natural result, competitors with rival processes have come forward. Some of these met with failure at an early stage of their career, but others are supplying oxygen to the public. This is by no means a state of things to be deplored from the consumer's point of view, if the product from the one source is as good as the other, for benefit generally arises from healthy competition. But when the rival product turns out to be not oxygen, but a half and half mixture of oxygen and air, with a slight excess of the latter, the competition is of a decidedly unhealthy character, and is correspondingly bad for the consumer. I recently obtained a sample of gas from a dealer, which on testing (with a Hempel absorption pipette, charged with metallic copper and ammonia) I found to be a mixture containing only 60.6 of oxygen. I next tested the illuminating value of this highly diluted oxygen with a limelight jet, and for sake of comparison, placed by its side a precisely similar jet supplied with Brin's oxygen, and, as might have been expected, the light given by the former was little more than one-half as intense as that afforded by the latter. With the good oxygen the lime cylinder was quickly pitted, whilst the other showed no symptom of destruction. It is also to be remarked that the consumption of the diluted gas was, for a given period, about one-third more—striving with both jets to get the best possible light—than that of good oxygen. On the same principle a mountaineer at a high altitude will pass more (rarefied) air through his lungs than he will when he is in the valley breathing that which contains the normal quantity of oxygen.

As this matter is of great importance to many workers, I trust that you may be able to find room in your valued publication for these words of necessary caution.

T. C. HERWORTH

45, St. Augustine's Road, Camden Square, N.W.,  
December 6

### THE STAR OF BETHLEHEM

IN the *Astronomical Journal* of November 26 we find the second of two very interesting articles written by Mr. J. H. Stockwell, bearing on the chronology of certain ancient events. In the introduction the author discusses and sums up some of the more important and historical dates which he has determined by calculations of ancient eclipses. He next refers to the help which may be obtained in the same direction by means of calculations of conjunctions of the planets, and quite appropriately to the present season points out that the appearance of the star of Bethlehem may have been due to the conjunction of the planets Venus and Jupiter, instead of Saturn and Jupiter, as was suggested on incomplete data by Kepler nearly three hundred years ago. We cannot do better than lay this part of Mr. Stockwell's communication before our readers.

"Although the heliocentric conjunctions of the planets occur with a considerable degree of regularity, and are also very easily calculated, the geocentric conjunctions are subject to many inequalities in the periods of their successive occurrences, so that it requires somewhat elaborate computations to determine accurately the character of any geocentric conjunction of two planets which occurred in ancient times. On account of the frequency of planetary conjunctions, and the indefinite manner in which they are usually described, it becomes a matter of very great difficulty to identify any particular conjunction unless it is associated with some other event whose data can be independently determined. A remarkable case of this character is given in the Bible, for Matthew informs us in the days of Herod the King 'there came wise men from the East to Jerusalem saying, "Where is he that is born King of the Jews? for we have seen his star in the East, and are come to worship him." From the subsequent inquiries and mandates of Herod the King concerning the time when the star appeared, we are led to infer that its appearance took place within two years preceding the death of Herod,

and it has been sought to explain the appearance of the star by means of a conjunction of the planets—the Creator employing celestial phenomena to proclaim 'the good tidings of great joy, which shall be to all people'.

"The illustrious Kepler was the first to suggest that the star of the wise men might be explained by means of a conjunction of the planets Jupiter and Saturn, and he even undertook to calculate the times when such conjunctions took place. Much has been said and written on the subject of the 'star of the wise men' during the past few years, but no important contribution to the natural history of the star has been made since the days of Kepler, nearly three hundred years ago. But the supernatural history and functions of such a star have been discussed in a very able and interesting manner by many writers in theological, literary, and semi-scientific periodicals during the past twenty years, and perhaps nothing of interest and importance can now be added to what has already been published on that subject.

"I find, however, that Kepler overlooked one important element of the problem in his calculations, and consequently left the natural history of the problem in an incomplete and unsatisfactory condition. I shall therefore here attempt to complete more fully what Kepler began, and show that the Biblical narrative concerning the 'star in the east' is better satisfied by a conjunction of Venus and Jupiter than by any of the conjunctions computed by Kepler.

"We have already seen that the death of Herod took place early in the year B.C. 4, and if we can now show that there was a very conspicuous conjunction of two bright planets, visible only in the east, within two years preceding that date, the hypothesis that such conjunction was the event referred to in the Biblical narrative will at least be rendered plausible, if not entirely legitimate, and for this purpose I have here undertaken the calculation of all the conjunctions of the planets which took place near that epoch. I shall first enquire whether there was a conjunction of the planets Jupiter and Saturn about that period of time which would satisfy the required conditions. The mean interval between two heliocentric conjunctions of Jupiter and Saturn is 7253.4638 days; and they were in mean conjunction B.C. 6, January 30. Now the time of true heliocentric conjunction may differ from the time of mean heliocentric conjunction by 241 days, on account of the inequalities in their elliptic motions, and by 23 days more by reason of the great inequalities of long period in their mean motions. But the time of geocentric conjunction of Jupiter and Saturn may differ from the time of heliocentric conjunction by 102 days, so that a geocentric conjunction may occur one whole year before or after the time of mean heliocentric conjunction. In the present instance I find that the true heliocentric conjunction took place B.C. 7, September 23, which is 129 days before the mean heliocentric conjunction, and that there were three geocentric conjunctions during the year B.C. 7, which took place as follows—

"The first conjunction took place June 7, in which Saturn passed  $1^{\circ} 4'$  to the south of Jupiter, the second conjunction took place September 18, in which Saturn passed  $1^{\circ} 2'$  to the south of Jupiter, and the third conjunction occurred on December 15, in which Saturn passed  $1^{\circ} 8'$  to the south of Jupiter.

"In the first conjunction the planets would have an elongation of about  $73^{\circ}$  to the westward of the sun, and would be seen during four or five hours in the east in the morning. The second conjunction took place near the time of opposition with the sun, and would be visible during the whole night, so that it could not properly be designated as a star in the east any more than a star in the west. In the third conjunction the planets would have an elongation of about  $84^{\circ}$  to the eastward of the sun, and could therefore appear only as evening stars.

in the west. Moreover, Saturn is not an especially bright planet, and consequently no one of these three conjunctions could have been very conspicuous in the heavens. The first conjunction was the only one that was visible in the east, but it occurred nearly three years before the death of Herod, it could hardly be said to satisfy the conditions required by the narrative. No other conjunctions of Jupiter and Saturn could possibly occur till about twenty years later, so that we may conclude with a light degree of probability that the phenomenon alluded to in the Bible was not occasioned by a conjunction of Jupiter and Saturn. Since the planet Mars is a conspicuous object when near its opposition with the sun, it may be well to inquire whether a conjunction of Mars and Jupiter might not occasion the phenomenon referred to. But since Mars is conspicuous only near its opposition with the sun, it is evident that any conjunction when in that direction would appear as a star in the west as much as in the east, and consequently it would not fulfil the required conditions. There was, however, a conjunction of Mars and Jupiter on March 5, B.C. 6, but at that the planet's elongation was only  $18^\circ$  to the eastward of the sun, and consequently could have been visible only in the west. But Mars was then so far from the earth, and so nearly in conjunction with the sun, that the conjunction would be wholly invisible. At the same time Saturn was not very far from Jupiter, and hence it was said there was a triple conjunction of the planets Mars, Jupiter, and Saturn in the spring of B.C. 6.

"It is evident without calculation there could be no conspicuous conjunction of Venus and Mars at any time, because Mars is not a conspicuous planet unless its elongation from the sun be greater than the greatest elongation ever attained by Venus, so that it would be a waste of time and labour to enter into the computations of any such conjunctions.

"It now remains to inquire whether the two brightest planets of the solar system, Venus and Jupiter, might not have been in conjunction within a short time before the death of Herod, and constitute the phenomenon alluded to in the biblical narrative, for it was the beautiful phenomenon presented by these two planets when in conjunction last February that suggested this investigation. Now the conjunctions of Venus with the sun occur with great regularity at intervals of about 584 days, while those of Jupiter at intervals of 399 days. Moreover, it may easily be shown that all geocentric conjunctions of Venus and Jupiter must take place within about 60 days before or after Jupiter's conjunction with the sun. Therefore, by tabulating the times of Jupiter's conjunction with the sun, we have only to investigate the longitude of Venus for a period of 60 days before or after that event in order to determine whether a conjunction of those planets will then take place. Now I find Jupiter was in near conjunction with the sun B.C. 6, March 29, while Venus was in conjunction on the preceding November 5, or 144 days earlier than Jupiter. Venus was therefore past her greatest western elongation, and was moving towards her superior conjunction, and she would overtake Jupiter on May 8, when their mutual elongations from the sun would be  $27^\circ 44'$  to the west. At that time the heliocentric latitude of Venus and Jupiter were  $3^\circ 21'$  and  $1^\circ 20'$  south, while their geocentric latitudes were  $1^\circ 40'$  and  $1^\circ 8'$  south respectively. It therefore follows that at the time of their geocentric conjunction Jupiter was only  $32'$ , or about the angular breadth of the moon to the northward of Venus, and as they were then to the westward of the sun, they would be visible only as a star in the east a couple of hours before sunrise. These two brightest planets in the sky would therefore at the time of conjunction, B.C. 6, May 8, be apparently very close together and produce a striking and beautiful appearance. The date also at which it took place being about 50 days less than two years before the death of Herod, harmonizes well with

the spirit and other conditions of the narrative, for it is probable that the mandate for the slaughter of the children of two years old and under was issued some months before his decease, and the limit of two years would leave an ample margin for any uncertainty as to the time of the appearance of the star as related by the Magi.

"There were no other conjunctions of Venus and Jupiter until the year B.C. 2, or nearly two years after the death of Herod, when there were two conjunctions, one of which occurred on August 31 and the other on October 4. The first of these was invisible on account of being too near the sun, but the second took place when Venus was nearly at her largest elongation to the westward of the sun.

"If the preceding calculations, and the references based on them, are correct, it follows that Christ was born as early as May in the year B.C. 6, and if He was crucified at the time of the paschal full moon, which occurred on a Friday, it must have taken place on April 3, in the year A.D. 33. And since any given phase of the moon is repeated on the same day of the week, and also within two days of the same time of the year, at intervals of 334 lunations, or 27 years, it follows there was no paschal full moon on a Friday between the years A.D. 6 and A.D. 60, except the one on April 3, A.D. 33, whence it would seem to follow that Christ was thirty-eight years old at the time of His crucifixion and death, and this would vindicate the sagacity of the Jewish doctors, who had recently affirmed that He (Jesus) was not then fifty (forty) years old."

#### FUJISAN<sup>1</sup>

ALL who remember the beautiful plates illustrating the volume on "The Great Earthquake of Japan, 1891," which was issued by the same authors a few months ago, will welcome the first instalment of a work which promises to illustrate, in a manner worthy of the subject, the magnificent volcanic phenomena of Japan. The present part contains ten plates, and is devoted to the illustration of the most famous and beautiful of all the Japanese volcanoes—Fujisan. The number of parts that the authors will publish will depend partly, we are told, on the encouragement they receive, and partly on the number of photographs that they have been able to secure during the past summer.

The photographs in the present part, which are all reproduced as permanent collotypes, 11 inches by 8 inches in size, are exquisite examples of what can be accomplished by this method of illustration, and show that Japan is certainly not behind any country in the world so far as the resources of the publisher go. Where all are so excellent, it is difficult to select any particular plate for especial praise, but one of the most remarkable is certainly Plate II, which gives a view over the great cloud-banks as seen from the summit of Fuji. Nothing can be more striking than the manner in which the effect of the great fleecy masses of vapour are reproduced, and here nothing whatever is lost from want of colour. The plate of greatest scientific interest is perhaps the last, which shows the interior of the crater of Fuji—a great pit 600 to 700 feet deep, with perpendicular walls. The sides are built up of rings of variously-coloured rocks, while snow rests in the sheltered hollows. The remaining pictures illustrate the sacred mountain as seen from different points of view, the graceful curves of its outline, the variation in the distribution of snow on its flanks, and the

<sup>1</sup> "The Volcanoes of Japan. Part I. Fujisan." By John Milne, F.R.S., Professor of Mining and Geology, Imperial University of Japan, and W. K. Barton, C.E., Professor of Sanitary Engineering, Imperial University of Japan. Plates by K. Ogawa. (Yokohama, Shanghai, Hongkong, and Singapore: Kelly and Walsh, Limited, 1892.)

character of the foreground, giving rise to great diversity in these eight pictures

As an example of these beautiful views, Plate IV —

"In the foreground, looking like a river, is the Lake of Hakone, at the back of which are hills some 4000 feet high. At the lowest gap in these hills is the Otome pass.

"Fujisan from above Hakone"—has been reproduced, although necessarily much of the delicacy of the original has been lost in the process by which it has been copied.

In the background, overlooking both lake and mountains, is the upper part of Fuji. This portion of the mountain is particularly conical, with sides sloping at an angle of

30°, its logarithmic sweep being lost behind the intervening mountains. The almost triangular notch in the snow-cap may possibly represent the scarp that is supposed to have been formed by the great earthquake of 1891, causing a strip of ground in unstable equilibrium to slip downwards." The reader should compare this view with that given in Plate IX, which shows the lake, with the reflection of the mountains behind, and the snow-covered Fuji rising in the background. This plate, and the view, Lake Kawaguchi, given on Plate V, are so delicate and faithful in their portrayal of water and atmospheric effects as to defy reproduction.

No attempt has been made by the authors to produce a scientific treatise, the information contained in the text being of a popular character, and the reader is referred to the Transactions of the Seismological Society of Japan for more detailed information on the subjects treated of. It is nevertheless true that the text published with these plates contains, as the authors claim for it, information not readily obtainable from other sources. The introduction gives a sketch of the volcanic phenomena of the Japan and Kurile Islands, in which we are informed that the number of volcanoes still preserving their form, and with distinct craters, is one hundred, distributed as follows.—In the Kuriles 23, in Yezo 28, in Honshiu 36, and in Kiushiu and the Southern Islands 13. Of these no less than 50 emit steam, while 39 are distinguished by their beautiful and graceful outlines. The number of great eruptions of which there is any published record is 233, the greater frequency, as with earthquakes, having been during the colder months of the year. One line of vents, which is more than 2000 miles long, begins in Kamsatka, passes through the Kuriles, Yezo, and down by Honshiu to the ever-smoking Asama. Here it is joined by a line branching away to the south-west, which runs through the great Fuji-san and Oshima, till it reaches the Ladrões, a distance of 1200 miles. The last line begins at, or near, the gigantic crater of Mount Aso, and extends 1300 miles through Formosa to the Philippines. Extremely basic rocks are rare, but so far as observations have gone, it may be said that the lava poured out from the northern vents is more acid in composition than the southern. All are magnetic, and lavas that will turn a compass-needle through 180° are not rare. By their decomposition, the soil of the country is in many places so filled with grains of magnetite, that a magnetized knife passed over the gravel of a garden path will be covered with a brush of this unoxidizable material.

The twelve pages devoted to the description of Fuji-san are replete with interesting information. The word Fuji is said (on the authority of the Rev John Batchelor, of Sapporo) to be a corruption of the Ainu word *Huchu*, which is the name of the "Goddess of Fire." Professor Milne ascended the mountain in 1880, and found that it was not quite extinct, as is usually supposed, for small quantities of steam were detected by him issuing through the ashes on the eastern side of the mountain just outside the lip of the crater. Von Fritsch and Ludecke have shown the lavas composing Fuji to be dolerites, and analyses by several chemists are given in this work. The beautiful and symmetrical outlines of the mountain are well known, but on the south side of the mountain there is an excrescence, at a height of 9000 feet, which was produced by the last great eruption in 1707. The recorded eruptions of the mountain are as follows—B.C. 301, 294, or 286, and A.D. 799, 802, 864, 937, 1021, 1082, 1329, 1560, 1627, 1649, 1700, and 1707. Professor Milne records the interesting observations made by him with a trometer or tremor-measure during a stay of five days on the top of Fuji. These observations tend to prove that the great mass of the mountain actually yields to force of wind playing around its summit. The height of Fuji-san is proved by various observations to lie between 12,400 and 12,450 feet.

The authors are to be congratulated on the excellence of this first instalment of a work which promises to be one of great scientific value. J W J

### THE GALILEO CELEBRATION AT PADUA

THE celebration of the three hundredth anniversary of the day on which Galileo began his labours as a Professor at the University of Padua was even more successful than had been anticipated. Its success was in every way worthy of the large number of scientific men who assembled to do honour to Galileo's memory, and of the great institution with which, as it remembers with veneration and pride, he was so intimately associated.

On December 6 the Rector, Prof C J Ferraris, received in one of the courts of the old University, adorned everywhere with portraits of the most illustrious professors, delegates from the Universities, the polytechnic schools, and Italian and foreign Academies, amounting to nearly a hundred, and amongst them many of those who shed most lustre on contemporary science. The University of Cambridge was represented by Prof George Howard Darwin, F.R.S., who also represented the Royal Society as Mr Norman Lockyer, its delegate, had been prevented from attending. The University of Oxford by Prof E J Stone, the Royal College of Physicians, London, by Sir Joseph Fayrer, F.R.S., the Chemical Society and British Association by Prof Ludwig Mond, F.R.S., the Harvard University, Cambridge, U.S.A., by Prof William James, and the Princeton University by Prof Allan Marquand; the University of Lund by Prof R A V Holmgren, the Astronomical Observatory of Paris by its Director, Prof F Tisserand, that of Berlin by Prof W Foerster, the Polytechnic Schools of Berlin, Karlsruhe, Monaco, Brunswick, Stuttgart, by Profs Lampe, Keller, Sohneck, Blasing, Lemcke, the University of Göttingen by Prof Voigt, that of Budapest by Prof Lanczy, that of Dorpat by Prof Schmourolo; that of Lausanne by its Rector, Prof Favay, the Academy of Paris by Prof Gariel, the Faculty of Letters at Grenoble by Prof de Croysal, the General Council of the Faculty at Nancy by Prof Molk, &c, &c. There were also delegates from the towns of Florence, Pisa, Venice, and representatives from the foremost Italian Universities, Academies, and Technical Schools.

The great academical celebration took place on December 7 in the large hall of the University, in the presence of the Hon Ferdinando Martini, Minister of Public Instruction, who represented the King of Italy. The ceremony was begun with a discourse prepared for the occasion by the Rector Magnifico, and devoted principally to a cordial expression of thanks to the King and to the Minister who represented him; to the foreign and Italian delegates, and to the ladies of Padua, who had given the University a most beautiful banner, on which were various emblems indicating the history of the University, the genealogical tree of the Galileo family, and the ancient inscription above the door of the University—*Gymnasium omnium disciplinarum*.

Next came the commemoration of Galileo by Prof Antonio Favaro, who has for nearly fifteen years devoted himself almost exclusively to the study of the life and works of Galileo, and to whom was confided by the Government the care of the national edition of the philosopher's works, under the auspices of the King of Italy. The orator kept his discourse within the limits marked out for him, speaking chiefly of Galileo at Padua. Constrained to leave the University of Pisa, Galileo had been welcomed in that of Padua, where he found the "natural home of his mind," a "theatre worthy of his talents." The conditions at Padua at that time were eminently favourable to Galileo's work, for the Venetian

Senate granted the lecturers the utmost liberty, and experimental methods, which could not be learned from books, had been practised at the University for more than a century. Galileo had many opportunities for the development of his genius, both in the lecture-room and in the home, in the preparation of scientific publications, and in the workshops of scientific instrument-makers both in Padua and Venice. To Venice he frequently went, attracted thither by the means it afforded him for study, by that grand arsenal which had already been sung by Dante, and which in his reputed Dialogues is spoken of by Galileo with admiration, but above all by the advantages he derived from scientific intercourse with eminent men who resided in the dominion. The culminating point of the discourse was naturally reached when the orator had to deal with the invention of the telescope, and with the astronomical discoveries made by means of it, the immediate result of which was the recall of Galileo to Tuscany. This did not aid Galileo in his glorious career, or help to protect him from the attacks which were for a long time made on him by invidious adversaries. Even some of his own servants changed at once to implacable and dangerous enemies, and at last he was involved in all the miseries which sprang from the memorable lawsuit. This led the orator to recall the fact that when the clouds assumed their most threatening aspect, the Venetian Republic, forgetting with real magnanimity whatever resentment it might have felt at Galileo's abandonment of his chair at Padua, offered to re-appoint him, and to print at Venice the work which had brought upon him so much trouble. He said also that a pleasant memory of Padua must have passed through the mind of the prisoner of the Holy Office, when there came to him his only comfort, the message from the favourite of his childhood, the nun who in Padua had tenderly cared for him during the first ten years of his youth.

After Prof Favaro's oration discourses were delivered by the foreign delegates, Holmgren, Fayrer, Darwin, Tisserand, Lampe, Keller, Foerster, Sohnecke, Blasing, Lemcke, Farey, Lanczy, Schmourlo, and by Italian delegates, Nardi-Dei, Mantovani-Orsetti, and Del Lungo. Then followed the conferring of University honours, of which seven had been set apart by the Council for seven men of science, one for each nation, all distinguished for their devotion to the studies in which Galileo excelled, viz Schiaparelli, Helmholtz, Thomson, Newcomb, Tisserand, Bredichir, and Gylden. The degree of philosophy and letters was given to the Minister Martini; of natural philosophy, and philosophy and letters, to the leading delegates. The ceremony was closed by the inauguration of a commemorative tablet in the large hall.

Of the other festivals connected with the celebration it would be out of place to speak here, and it will be better to add a list of the publications which have been issued on the occasion. The oration read in the Great Hall by Prof Favaro has been published, with the addition of twenty-five facsimiles of documents containing the various decrees of the Senate concerning Galileo, the date of the early prelections given by him at regular intervals, several autographic records of Galileo, chosen in order to give a more exact idea of what are the most precious materials for his biography, the frontispieces of the various publications issued by Galileo, or relating to the time of his sojourn in Padua, the geometric and military compass, the writing presenting the telescope to the Doge, and the first observations of the satellites of Jupiter. A portrait of the great philosopher, from a painting which represents him at the age of forty, taken in 1604, is prefixed.

By favour of the University there have also been published two other works, one containing all the notices of the studies at Padua in 1592, the other proving which

was the house inhabited by Galileo and the place in which he made his astronomical observations. The ancient Academy of Padua, among whose founders Galileo is numbered, has issued a publication in which are collected several works dedicated to his memory, and the students of the University have sought to perpetuate the remembrance of this festival by the publication of a "unique number," bringing together all the documents relating to the sojourn of Galileo in Padua, collected from all quarters. These publications will serve as suitable memorials of a great and most interesting celebration.

ANTONIO FAVARO

#### SIR RICHARD OWEN

IT is with great regret that we record the death of Sir Richard Owen. He died on Sunday, after a lingering illness, at Sheen Lodge, Richmond Park, in his eighty-ninth year. In publishing his portrait in the series of "Scientific Worthies" (*NATURE*, vol. xxii p. 577) we have already presented an estimate of his work and of his place in the history of science. It is only necessary now, therefore, to recall some of the leading facts of his career.

He was born at Lancaster on July 20, 1804, and received his early education at the grammar school of his native place. Afterwards he matriculated at the University of Edinburgh as a medical student. In 1825 he joined the medical school of St Bartholomew's Hospital, London, and in 1826 he took his diploma at the Royal College of Surgeons. His professional studies having been completed, he began to practise in Serle Street, Lincoln's Inn Fields, but the bent of his mind was towards purely scientific investigation, and he soon had a good opportunity of exercising his powers. Dr Abernethy, with whom he had acted at St Bartholomew's as a dissector, had recognized his ability, and, in accordance with the advice of this famous surgeon, he was invited in 1828 to undertake the task of cataloguing the Hunterian collection at the Royal College of Surgeons. The invitation was accepted, and in 1830 the first catalogue of the invertebrate animals in spirits was published. In the same year Owen read at the first meeting of the Zoological Society's committee of Science a valuable paper on the anatomy of the orangutan, and afterwards he made many important contributions to the Society's Transactions and Proceedings. He was also well known as a reader of papers before the Medical Society of St Bartholomew's and the Medical and Chirurgical Society of London. In 1832 appeared his well-known essay on the Pearly Nautilus (*Nautilus Pompiilus*), in which he gave most striking proof of his power of interpreting the facts of natural history in a thoroughly philosophical spirit.

Before he was thirty years of age Owen had achieved so good a reputation that in 1834 he was appointed to the newly-established chair of comparative anatomy at St Bartholomew's Hospital. Two years afterwards he succeeded Sir Charles Bell as professor of anatomy and physiology at the Royal College of Surgeons, and he was elected to the newly-established Hunterian professorship at the Hunterian Museum. He also became conservator of the Hunterian Museum on the death of Mr Clift, whose daughter he had married. He had gradually been withdrawing from the practice of his profession, and ended by devoting the whole of his time and energy to scientific work.

His connection with the Royal College of Surgeons lasted for twenty years, and during this period he achieved results which placed him in the front rank of original investigators. In the article to which we have referred we have already indicated the nature and importance of these results, and need not go over the same ground again. It must suffice to mention the completion, in five volumes, of his catalogue of the Hunterian

collection, his "Odontography", his Lectures on Comparative Anatomy and Physiology; his "Archetype and Homologies of the Vertebrate Skeleton", his memoirs on "The Nature of Limbs" and on "Parthenogenesis", his monograph of British fossil reptiles, and his papers on the fossil birds of New Zealand, and on some fossil mammals of Australia. In 1856 he was appointed Superintendent of the Department of Natural History in the British Museum. How splendidly he fulfilled the duties of this position all the world knows. He fought steadily and earnestly to obtain proper accommodation for the magnificent collection placed under his charge, and to him, more than to any one, Great Britain owes the fact that this particular set of her scientific treasures is now so securely preserved and so finely displayed. The practical duties of his office were not allowed to interrupt his scientific researches, and year after year he continued to give fresh evidence of the astonishing range of his knowledge and of his remarkable capacity for far-reaching and brilliant generalization. Among the writings of this period are his Manual of Paleontology, and his memoirs on the classification and geographical distribution of mammals, on the British fossil reptiles of the Liassic formations, ichthyosaurs and plesiosaurs, on the British fossil cetacea of the Red Rag, on the British fossil reptiles of the Mesozoic formations, pterodactyls, and on the fossil reptiles of South Africa.

In 1883 he resigned his official position, but he did not cease to interest himself in the studies in the prosecution of which he had displayed so commanding a genius. In 1884 he issued in three volumes his great "History of British Fossil Reptiles," and until a comparatively recent date he submitted to the Royal Society from time to time papers embodying the more important results of his labours.

In the course of his long career Owen did much good service as a member of various Commissions, and it is scarcely necessary to say that honours of many different kinds were conferred upon him. About these matters we have given all necessary information in our previous article. Owen was very far from being content merely with the collection and classification of facts; he sought also to bring out the ideas in which his facts seemed to him to find their ultimate significance. He was unable to adopt the theory of evolution as presented by Darwin, but his researches did much to prepare the way for the general and rapid acceptance of Darwin's hypothesis, since it was felt that there must be some strictly scientific explanation of the affinities by which he had shown vast groups of animal forms to be allied to one another. Apart altogether from its speculative aspects, his work is universally acknowledged to be of high and enduring value, and there can be no doubt that he will rank among the strongest and most impressive figures in the intellectual history of the nineteenth century.

He desired that his body should be buried beside that of his wife in Ham Churchyard, and his wish is, of course, to be complied with. At the funeral, which will take place to-morrow (Friday), there will be representatives of all the learned societies with which he was connected.

#### NOTES.

THE following memorial, numerous signed, has been presented by Sir Henry Roscoe to the Right Hon. the Earl Cowper, Chairman of the Royal Commission on the Gresham University:—The undersigned desire hereby respectfully to record their strong opinion that the foundation of a Teaching University for London, without due provision being made for higher Education and original Research, would be unworthy of the Metropolis, and would entail the neglect of an admirable opportunity for promoting the advancement of Science and

NO. 1268, VOL. 47]

Learning. The signatures cannot fail to command attention. The following learned Societies are represented by their Presidents.—The Royal Society, the British Association for the Advancement of Science, the Royal Dublin Society, the Royal Society of Edinburgh, the Iron and Steel Institute, the Physical Society, the Institution of Electrical Engineers, the Institute of Mechanical Engineers, the Chemical Society, the Royal Horticultural Society, the Pharmaceutical Society of Great Britain, and the Institute of Chemistry of Great Britain and Ireland. Eton College, Harrow School, Rugby School, and St. Paul's School are represented by their head-masters. There are also representatives of the University of Oxford, Cambridge, Edinburgh, Glasgow, Aberdeen, and St. Andrews, the Victoria University, the British (Natural History) Museum, the Royal College of Science, London, University College, London, Mason College, Birmingham, Durham College of Science, Firth College, Sheffield, University College, Dundee, University College, Bristol, City and Guilds of London Central Institution, the Royal College of Science, Dublin, and the Pharmaceutical Society of Great Britain. A special group of signatures consists of the names of a number of Fellows of the Royal Society.

SIR JOSEPH LISTER, Sir Henry Roscoe, and Prof. Ray Lankester, will represent the Royal Society at the Pasteur celebration in Paris on the 27th inst. Captain Abney has been invited to represent the Society at the 150th anniversary of the American Philosophical Society in May 1893.

WE are glad to see that a movement has been started for the purpose of securing that due honour shall be done to the memory of Jean Servais Stas, one of the most illustrious of modern chemists. It is proposed that a new edition of his writings shall be issued, his memoirs, notes, and reports being grouped in their proper order, and that a commemorative monument shall also be erected. An influential committee, representing science in all parts of the world, has been appointed to take the necessary steps. Subscriptions will be received by M. L. Errera, 1, Place Stéphanie, Brussels.

THE Committee of the International Electrical Exhibition to be held at Milan in 1894 proposes, according to *La Lumière Electrique*, to offer a prize for the most important invention or discovery in the province of electricity, especially in connection with the transmission of energy to a great distance, and its distribution and transformation for industrial uses.

SUCCESSFUL experiments have been made in France relative to the introduction of telephones for use in warfare. The telephonists are organized in sets of two men, each set being provided with equipment for a mile line. The very simple receiving and transmitting apparatus are attached to the military cap, and the wire is on reels in a sort of breast-plate, the whole being so light that a man's ordinary equipment weighs less than six pounds.

THE tunnel at Niagara Falls is finished, and the power plant will be in operation by next March. It is expected that a current of 45,000 electric horse-power will be transmitted from there to Buffalo, and 30,000 to other points.

M. MAURICE MALLET, in *L'Aéronaute*, describes what he claims to be the longest balloon ascent on record. His balloon, "Les Inventions Nouvelles," started from the gasworks of La Villette, Paris, on October 23, and the voyage terminated at Walhen, in Central Germany, at 6 a.m. on the 25th, after a total journey of 36 hours 10 minutes above ground. The flight was interrupted several times by the snow which fell in the higher regions of the atmosphere. When lower strata were reached, the snow melted, and the balloon regained its ascending power. During one of these descents it was stopped and examined by

a Prussian *gendarme*, who had followed it at a gallop for some distance. The route passed over part of Belgium, the Taunus, and the Odenwald, and the towns of Metz and Frankfurt were recognized in passing.

THE "Annals of the Harvard College Observatory" contain a discussion by H. H. Clayton of the cloud observations made at Mr. A. L. Roitch's observatory at Blue Hill, Massachusetts. One of the most noticeable facts brought out by the measurements of cloud heights and velocities, which have been conducted with great care, is the difference in height between the same clouds in summer and winter, the clouds, with few exceptions, being lowest in winter. The bases of the cumulo nimbus clouds, however, are generally lower in summer, while, at the same time, their tops are higher than in winter. The heights of the different clouds were found to maintain an almost constant ratio to each other. The mean velocities recorded showed that the entire atmosphere moves twice as fast in winter as in summer. The mean velocity of the highest clouds in winter was about 100 miles an hour, the extreme velocity amounted to 230 miles an hour, from which it appears that the upper currents are much more rapid over America than over Europe, which possibly explains the greater velocity of the storms in America. As regards the directions of cloud movement, the tables show that from the highest clouds to the earth's surface, the prevailing wind is west, above 4000 metres more than 90 per cent of the observations show the clouds from some point between south west and north-west inclusive. In the cirrus and the cumulus regions, and near the earth's surface, the prevailing direction is from a little north of west, but in the intermediate levels, from a little south of west, the excess of the southerly component in these regions being possibly due to the influence of cyclones.

THE weather during the past week has been generally very dull, and scarcely any rain has fallen over the southern parts of the kingdom. Between Friday and Monday there were several depressions to the northward of our islands, passing in an easterly direction, which caused very severe gales and high seas on the coasts of Scotland, the difference on pressure on Sunday between the north and south of our islands being more than an inch. During the first part of the period the temperature was unusually high for the season, the maxima exceeding 55° in some parts, and the night minima were occasionally higher than the average daily maxima for the month, subsequently, however, a decided fall occurred, with fog and mist in most parts of England, while in Scotland hail and sleet showers were experienced. The *Weekly Weather Report* of the 17th instant shows that for that period the temperature was from 2° to 4° above the mean. Rainfall exceeded the mean in the north of Scotland only, and just equalled it in the north of Ireland, in all other parts there was a deficiency. Bright sunshine was much less prevalent than during the preceding week, although in most parts of England the amount exceeded the average.

PROF. COLE writes from Dublin that the afterglow in the west and zenith on Saturday, December 17, was of a superbly brilliant character. Mr. R. Langton Cole observed that in London on December 15 the whole sky was covered by the glow, which was deeper all round towards the horizon.

AN interesting lecture on "Water and Water Supply" was delivered last week at the London Institution, by Major L. Flower, of the Sanitary Institute. As an instance of the important part which water played in the economy of nature, he mentioned that if a man weighing 140 lbs. were placed under a hydraulic press and squeezed flat, the result would be 105 lbs. of water, and only 35 lbs. of dry residue, which was a fact for congested people to reflect upon. Major Flower gave some interesting facts about the rainfall of England. It is, of course,

highest in mountainous districts, the maximum fall being found in Cumberland, where the record for six years shows an annual rainfall of 165 in. The lowest in England is between Biggleswade and Bedford, where it reaches only 20 in. London and the east coast average about 25 in. Speaking of drinking water, Major Flower said the best way to get it was to bottle it at the fountain head and have it delivered in bottles, which had been done already and might be done to a greater extent in the future.

MR. W. F. HOWLETT writes to us from Pahiataua, New Zealand—"Can you inform me what is now sold in England as gum arabic? I used to be able to buy a soluble gum, what I get now is the same in appearance, but it will not dissolve. It swells up, truly, but will not form a homogeneous filterable solution. It would be a great boon to small buyers if such things were sold under their proper names. Am I right in supposing that since the Soudan trouble gum arabic has disappeared from commerce?"

A VERY interesting report on artesian boring, by Mr. J. W. Boulton, is included in the volume containing the annual report of the Department of Mines and Agriculture, New South Wales, for the year 1891. Mr. Boulton shows that, as a rule, artesian waters are suitable for irrigation purposes, only those heavily charged with salt or alkaline matters being unsuitable, and he can see no reason why such irrigation should not be an element of immense value, deserving the utmost consideration in connection with the development of that north western portion of the colony, where the fertility and recuperative powers of the soil are so wonderfully illustrated by the growth of feed after rainfall at the proper season. The average quantity of water required for the irrigation of grain crops, based upon the experience of other countries, may be roughly estimated at 72,600 cubic feet, or 543,485 gallons per acre. One inch of rain would equal 3630 cubic feet, or 22,622 gallons per acre. A rainfall of 20 inches would therefore yield 72,600 cubic feet, or 543,485 gallons per acre. 640 acres would consequently require 46,464,000 cubic feet, or 347,830,400 gallons upon them as an equivalent to 20 inches of rain. When it is considered that the flow per diem from the Native Dig Artesian Bore, 45 miles from Bourke, is approximately 2,000,000 gallons per diem, or 730,000,000 gallons per year, it will be seen that upon the foregoing basis a supply of water equal to a rainfall of 40 inches per annum, per 640 acres is available, or that an area of considerably over 1280 acres can be supplied with water equalling a rainfall of 20 inches per annum.

THE Cambridge Local Lectures Syndicate have just issued an announcement of their next Summer Meeting of University Extension students, to be held at Cambridge in August, 1893. The programme is a large and varied one, and a number of well-known lecturers have already promised their services. Among the scientific lecturers we notice the names of Sir Robert Ball, Sir H. E. Roscoe, Mr. Patison Muir, and several of the best known of the Cambridge Extension lecturers. Cambridge has always laid great stress on the importance of providing, as far as possible, practical work in science as well as theoretical teaching. It has seldom been found possible to arrange much practical work in connection with the lectures given in the provinces, chiefly on account of the difficulty of finding laboratory accommodation. But students who can spare a fortnight—or, better still, a month—have now the opportunity of coming to Cambridge and seeing, at any rate, something of the resources of the University laboratories. Even two or three weeks' work in a well-equipped laboratory may easily be a revelation to a student who has hitherto learnt his (or her) science from books or lectures. The laboratory work has always formed an important and highly appreciated part of the

**Cambridge Summer Meetings** Next year no less than five practical courses are promised, viz. in physics, chemistry, botany, physiology, and palæontology, thus providing for a considerable variety of taste, and for the accommodation in the laboratories of a fairly large number of scientific students. Another feature in the programme is an entire novelty. It is proposed to give a series of short courses of lectures on the growth of various sciences—astronomy, physics, chemistry, and geology—to illustrate from different points of view the methods by which discoveries are actually made, and science makes progress. These will be accompanied by a short theoretical course on scientific method. The sciences selected only cover a small portion of the whole field, and some aspects of scientific method—such as classification—will obviously scarcely be represented. The organic sciences generally are left out, and may possibly form the groundwork of a similar scheme on some future occasion. The idea of illustrating scientific method by the history of science is a familiar one, and is the basis, for example, of Whewell's great books on "The Philosophy and the History of the Inductive Sciences." Few men, however, possess the encyclopædic knowledge of science which Whewell had, and the progress of science since his day would make such a task as he undertook well nigh impossible for a more modern writer. The Cambridge Syndicate do not attempt to find a Whewell, but hand over the history of each science to competent specialists, and hope to give real unity to the whole by the lectures on method, in which the lessons taught by the history of the various sciences will be brought into a focus, and made to lead up to general principles. The experiment is certainly an interesting one, and we shall watch with some interest to see how it succeeds. The programme includes also lectures on history, literature, art, and other subjects. But we have dwelt only on the science as being of special interest to our readers.

In the Herz oscillator, as used hitherto, the spark discharge of a Ruhmkorff has been produced in air between two balls. MM. Sarasin and de la Rive lately thought (*Arch. de Sciences*) to place the balls in an insulating liquid, and they find that this gives a more intense effect in the resonator. Olive oil does best, oil of turpentine, liquid paraffin, and petroleum were also tried. Placed near the oscillator the resonator gives quite a bright spark, and at about 30 ft. distance, with a resonator of large diameter, the spark is strong enough to be visible a good way off.

ATTEMPTS are being made to create a silk-producing industry in the district of Nicolaïeff, in South Russia, and, according to the British Vice-Consul at Nicolaïeff, the result is not unlikely to be satisfactory. He says that the mulberry tree, for the growth of which the soil and climate are well adapted, flourishes wherever it is planted, and that with very little trouble or expense every little plot of ground, now yielding nothing more than a crop of weeds, might in a short time be transformed into a remunerative feeding-ground for the silkworm. The matter has been taken in hand by a society, and every encouragement is given to the peasants and poorer classes to take advantage of the opportunities provided for them. If seriously followed up, the scheme may, the Vice-Consul thinks, prove a source of revenue to many a poor family, and eventually be the means of establishing a large and flourishing industry.

At a recent meeting of the Trinidad Field Naturalists' Club there was some discussion as to the question whether the bite of the tarantula (*Mygale*) spider is poisonous. Mr. C. W. Meaden, writing to the Club's journal on the subject, describes an incident which came under his own observation. Early in the present year he had a gang clearing some land after burning, and on visiting them one afternoon he saw a black tarantula dart from a heap of bush and deliberately bite one of the

prisoners on the heel and then scamper away, which it did with safety to itself, although chase was made after it. The spider seemed to be in an angry mood at being disturbed in a favourite haunt for food and shelter. The bite drew blood, about two or three drops. A Trinidad labourer's foot is thick enough almost to resist an auger, yet the spider managed to penetrate, so it may safely be asserted it was in earnest. Immediately the bite was given a shout went up, "The man is bitten by a big black spider—a tarantula!" This made the bitten one almost frantic with fright, and he cried out piteously, "Me God, me go die in gaol, me God," &c. Mr. Meaden took him to the infirmary, some 300 yards distant, and the sufferer carried his heel in his hand, &c. hopped all the way. His foot was fomented with hot water, and spirits of ammonia were applied, with the addition of a little liquid ammonia, and he received a dose of ether mixture. About two hours afterwards he ate his dinner heartily and slept well at night. He complained of no pain in the morning, and went to work as usual. There was no local swelling or inflammation, and but little pain at any time. Fright was the only ill effect.

SOME interesting results in application of cold have been recently recorded. Thus M. d'Arsonval has found that while with rising temperature, microbes die before soluble ferments, with lowered temperature the opposite occurs. The invertase of beer yeast cooled to  $-40^{\circ}\text{C}$ , does not lose its power, but it is destroyed as a ferment at  $-100^{\circ}$ . On the other hand, the yeast itself cooled to  $-100^{\circ}$  is still active. M. Raoul Pictet has lately observed that at  $-150^{\circ}$  all chemical reaction is suppressed. Thus, if sulphuric acid and potash are brought together at this temperature, they do not combine. Litmus paper, introduced, keeps its colour. Curiously, it is possible to restore their energy to these inert substances, by passing an electric current, and the current passes readily whatever the substances, at  $-150^{\circ}$  all bodies are good conductors. The disappearance of affinity at a low temperature can be utilized to get absolutely pure substances, and M. Pictet has thus obtained alcohol, chloroform, ether, and glycerine.

SOME good notes on the Shuswap people of British Columbia, read before the Royal Society of Canada by Dr. George Dawson, F.R.S., are now printed in the Society's Transactions, and have also been issued separately. In an interesting section on the superstitions of the Shuswaps he notes that they have a singular idea about certain small lizards. A man who sees one of these creatures is supposed to be followed by it wherever he may go during the day, till at length, when he is asleep during the following night, it finds him, and entering his body, proceeds to eat out his heart, so that he quickly dies. The late Mr. Bennett, of Spallumcheen, told Dr. Dawson in 1877 that the Indians employed by him in making a ditch for purposes of irrigation, on coming into camp in the evening, would jump several times over the fire in order to lead the possibly pursuing lizard to enter the fire and be destroyed in attempting to cross. He also noticed that they carefully tied up the legs of their trousers when retiring. If while at work during the day they saw one of these little lizards, which appeared to be abundant in that locality, it would be caught in a forked twig, the ends of which were then tied together with a wisp of grass and the butt end of the twig afterwards planted in the soil. Thus treated, the lizard soon died and became a natural mummy. If during the progress of the work any one found and carelessly tossed aside one of these lizards, the Indians would throw down their tools and search diligently until they found it, and secured it in the manner just described. Dr. Dawson thinks that this superstition must be widespread among the Indians, for it was afterwards related to him in identical form by a man of the Nicola River, who further pointed out a small lake, singularly

situated on the summit of a high ridge about a mile and a half south of the mountain named Za-kwās'-ki, as a noted resort—possibly the only place known to the man—of this peculiar animal. He described it as being a few inches in length and nearly black. Za-kwās'-ki, to which other stories attach, is south of Nicola River, at the source of the Nicomene River.

A COMMON impurity in many seeds which are used as food for live-stock is the seed of corn-cockle (*Agrostemma githago*). Notably is this the case on the Continent, and especially in Hungary, where the refuse from the machines used in cleaning grain consists chiefly of cockle-seed, and is largely used in feeding swine. It appears, as a rule, to have no ill effect upon these animals. Upon other animals, however, it sometimes has serious and even fatal effects, especially upon calves and dogs. According to Kobert (*Landw. Centralbl. Provinz Posen*, 19) it would appear that the seeds contain a glucoside—saponin  $C_{22}H_{34}O_{18}$ —which acts as a poison either when eaten in the form of cockle-seed or when introduced into the blood. Various animals are affected in different degrees, but dogs, cats, and birds soon die when fed upon the seed. The poison decomposes the blood, dissolving the red corpuscles, and also destroys the sensitive albuminoid portion of the nerve elements. Heating to  $50^{\circ}\text{C}$ . decomposes the saponin, and renders the seed harmless. Since this glucoside is found to lie only just below the surface of the seed, Kobert suggests that the seed should be coarsely ground and the outer husk separated, to cook the meal would be a still safer precaution. A good deal of cockle-seed comes into the port of Hull, chiefly, it is presumed, amongst grain which has not been cleaned. From such seeds as linseed it is removed by screening before pressing, but it is too often found in the cake which results after the oil is expressed from the linseed. A considerable quantity of corn cockle is handled in Hull, whatever its ultimate destination may be, and it sometimes occurs in feeding stuffs in far too large a percentage to be considered as an accidental impurity. Its use in admixture (as impurity or otherwise) with other feeding stuffs is strongly to be deprecated so long as there is the slightest risk attending its consumption by any domestic animal. Its detection is very easy, the peculiar rough husk of the seed being characteristic, the husk, after clearing with dilute sulphuric acid, and then with caustic soda, and examined under a low power of the microscope, will exhibit dark-red convoluted markings which distinguish it clearly from the husk of any other well-known seed.

It is a well known fact that sea anemones have a sense by which they recognize food. This has been studied recently by Herr Nagel at the Zoological Station in Naples, and he has endeavoured to localize it. Among other experiments, a small piece of a sardine was brought carefully to the tentacles of one of these animals, the tentacle first touched, then others, seized the food and surrounded it, and the morsel was swallowed. A similar ball of blotting-paper saturated with sea-water, brought near in the same way, was not seized. If, however, the ball was soaked in the juice of fish, it was seized with the same energy as the piece of fish, but often liberated again after a time without being swallowed. Blotting-paper saturated with sugar acted like the other, but more weakly. If saturated with quinine, it was refused, the tentacles drawing back. On the outer surface of the body, as also in the part between the tentacles and the mouth, quinine had no effect, nor had coumarin, vanillin, or picric acid. When a piece of meat was placed in or near the mouth of a widely-open animal, no notice was taken of it, it was only seized when the tentacles were touched. Thus the sense of taste seems to be in these alone. Cutting the tentacles did not evidently give pain, but these organs appeared sensitive to heat and to touch, so that they appear to be the seat of three senses.

MR JOHN MURRAY has published a fourth edition of Dr W. Fream's "Elements of Agriculture." The work was originally issued at the beginning of the present year, and two editions were sold out before the end of January. The third edition has for some time been out of print. The book has now been thoroughly revised, and enriched with a completely new set of illustrations.

A NEW edition of Dr John Casey's "Sequel to the First Six Books of the Elements of Euclid" has been issued as a volume of the Dublin University Press Series. The work has been edited by Prof. P. A. E. Dowling, by whom it has been carefully revised and considerably enlarged. The editor has obtained much valuable aid from Prof. Neuberg, of the University of Liège.

MESSRS BLACKIE AND SON have issued a second edition, revised and enlarged, of Mr J. McGregor-Robertson's "Elementary Text book of Physiology."

A FURTHER communication concerning the nature and properties of hydroxylamine,  $\text{NH}_2\text{OH}$ , is contributed to the *Recueil des travaux chimiques des Pays Bas* by M. Lobry de Bruyn, whose isolation of the free base was described in our note of vol. xlv p. 20. It may be remembered that pure hydroxylamine was found to be a solid substance, crystallizing in colourless thin plates or needles, which are extremely deliquescent. So powerful indeed is the affinity of hydroxylamine for water, that the crystals rapidly dissolve when exposed to the air, in the moisture attracted. The crystals melt at a temperature of  $33^{\circ}$ , and the liquid boils at  $58^{\circ}$  under the reduced pressure of 22 millimetres. If the liquid is heated under ordinary atmospheric pressure in contact with the air, it explodes with great violence when a temperature between  $60^{\circ}$  and  $70^{\circ}$  is attained, if the experiment is carried out in a vessel from which air is excluded, the liquid may be heated as far as  $90^{\circ}$  without accident, regular decomposition into gaseous products occurring at this temperature. Explosion, however, usually follows at once if this temperature is much exceeded, and generally after a short time if the source of heat is removed as soon as the thermometer has reached  $90^{\circ}$ , inasmuch as the decomposition which is induced at this temperature is accompanied by evolution of heat. The crystals are without odour. They react with considerable violence with the halogen elements, the reaction in the case of chlorine being accompanied by production of flame, the products do not appear to have been investigated as yet beyond ascertaining the presence among them of the halogen acids. Metallic sodium also vigorously attacks hydroxylamine, brilliant incandescence occurring. Warm zinc dust reduces it to ammonia so rapidly, that if any considerable quantities are employed a violent explosion follows. Highly oxidized compounds, such as potassium permanganate, chromates, bichromates, or chromic acid react with crystals of hydroxylamine, as may be expected, in a most energetic manner, brilliant flame being produced often accompanied by detonation. Chlorates, perchlorates and bromates behave similarly in the presence of a drop of sulphuric acid. Hydroxylamine liberates iodine from iodic anhydride, and rapidly reduces iodates to iodides. Dehydrated sulphate of copper inflames in contact with the crystals of the base, and powdered nitrate of silver is reduced to metallic silver. Addition of trichloride or pentachloride of phosphorus to the crystals likewise brings about ignition. Hydrogen peroxide oxidizes hydroxylamine to nitrous acid. These reactions, selected from a large number which M. de Bruyn describes, amply demonstrate the remarkable chemical energy with which anhydrous hydroxylamine is endowed. It is interesting to learn that the melted substance is capable of dissolving a considerable volume of ammonia gas. Moreover, carbon dioxide and sulphuretted hydrogen are so soluble in melted hydroxylamine that

viscous liquids are produced which remain liquid even at  $-10^{\circ}$ . As regards the preparation of the base, M de Bruyn has now succeeded in obtaining a hundred grams of the pure crystals from a little more than a kilogram of the hydrochloride, by the method described in our previous note above referred to.

THE additions to the Zoological Society's Gardens during the past week include a red and yellow macaw (*Ara macao*) from Central America, presented by the Rev T N Talfourd Major, two gold pheasants (*Thaumalea picta* ♀ ♀) from China, an Alpine Chough (*Pyrrhocorax alpinus*), European, purchased

### OUR ASTRONOMICAL COLUMN

COMET HOLMES (NOVEMBER 6, 1892).—The following ephemeris, taken from *Astronomische Nachrichten*, No 3131, gives the position for Comet Holmes for the ensuing week.—

Berlin, Midnight

1892	R. A. (app.) h m s	Decl (app.) ° ' "	Log r	Log Δ

29	1 1 21	34 19		

M Deslandres, in *Comptes rendus* for December 12 (No 24), informs us that on November 21 he obtained a photograph of this comet between 10h 40m and 11h 20m Paris mean time, showing distinctly "un commencement de dédoublement." Owing to the bad weather no other negatives were taken until December 10, but although the time of exposure was an hour, the comet's impression was not obtained, thus confirming the present eye observations that its intensity is slowly decreasing.

COMET BROOKS (NOVEMBER 20, 1892).—The following ephemeris of Comet Brooks is that obtained by Berberich, and varies a little from that given last week, as will be seen by comparing the values for December 22, with those given last week.—

Berlin, Midnight

SWIFT'S COMET.—*Knowledge* for December 1 contains three most interesting photographs of Comet Swift, taken by Prof. Barnard at the Lick Observatory on April 4, 6, and 7 respectively. These photographs, which are obtained from the original negatives after an enlargement of 2½ times, show what good photographic work can be done even with small instruments when exposures are somewhat lengthened. In this case a 6-inch Willard lens of 31 inch focal length was strapped on to the tube of a 6½-inch equatorial, and the exposures given amounted to 60, 65, and 50 minutes. The ordinary driving-clock, combined with a slight hand movement at the eye end, were all that was required to compensate for the diurnal and proper motion of the comet. The star trails on the plates pointed out then the comet's proper motion. Although these photographs were taken at such short intervals the changes recorded are most striking, the pictures bearing very little likeness to one another. On this point Prof. Barnard says "Had they been drawn by the most competent observer, most astronomers would leave their remarkable differences to the unskilful hand of the artist, for there is absolutely no resemblance among them." The photographs here referred to are from a series taken at Mount Hamilton, and in examining them he mentions that in the case of this comet he has been led to forcibly believe that in a comparatively short period there occurred a rotation of the tail "upon an axis through the nucleus."

NO. 1208, VOL. 47]

ULTRA-VIOLET SPECTRUM IN PROMINENCES.—In the current number of the *Memorie della Società Degli Spettroscopisti Italiani*, Prof. G. E. Hale communicates a note on some photographs of the ultra-violet region in the spectra of solar prominences. On October 15 at 3h 15m a photograph of the spectrum of a metallic prominence was obtained, which contained as many as 74 bright lines in the ultra violet between wave-lengths 3970 and 3630. The photograph, besides displaying all the lines previously recorded by Prof. Hale and M. Deslandres, contained 32 additional lines which had not been previously known. The following table shows their respective wave-lengths, which are to be regarded yet as only approximate.—

λ	λ	λ
3964	3863	3724 3
3956 9	3850 5	3716 9
3945 2	3813 5	3710 3
3938 1	3774	3699 5
3913 5	3767 1	3683
3905	3758	3681
3895 5	3757	3679 5
3893 8	3749 7	3674 2
3891	3741 7	3662 2
3878 8	3733 3	3647 8
		3632
		3630 8

Besides these lines the photograph shows traces of the lines λ 3807 2, 3802, 3764, 3763, 3758 2, 3709 5, 3707 8, 3676, 3643.

EPHEMERIS FOR BODIES MOVING IN THE BIELA ORBIT.—In *Astronomical Journal*, No 281, Dr Chandler communicates an ephemeris for the use of those wishing to search for bodies which may be moving in the orbit of Biela's comet. The ephemeris is given for every eight days. It is based on the orbit obtained by Micher, who calculated the principal perturbations up to 1866. In the present computations Dr Chandler has not taken into account any disturbance that may have been produced by the proximity of the planet Jupiter, or any perturbation that might have ensued from an approach to our earth. The values are given up to the end of February, 1893.

MADRAS MERIDIAN CIRCLE OBSERVATIONS.—The Government of Madras has lately issued the results of observations of the fixed stars, made with the meridian circle during the years 1874-76. During this interval no change whatever was made either in the instrument or in the methods of reduction. The volume gives the instrumental corrections for these years, the separate results of observations for each year, with the mean positions of the stars brought up to January 1 of each year, and corrections to the Nautical Almanac stars for the period in question.

### THE JUBA RIVER

AT the meeting of the Royal Geographical Society on Monday evening, Commander F. G. Dundas, R.N., read a paper describing his ascent of the Juba river. This was the first serious attempt to explore the river since Von der Decken's ill-fated expedition in the *Guelph* in August, 1865. The stern-wheel steamer *Kenia*, belonging to the Imperial British East Africa Company, under the command of Captain Dundas, crossed the bar of the Juba on April 25, 1892, an operation of much danger, as the vessel was exposed broadside on to heavy rollers, the depth at high water is only one fathom, and the water swarms with sharks and crocodiles. The coast Somalis lined the bank with hostile movements, as soon as they saw that the vessel was to go up the river, and detained the expedition for a fortnight, until a message was sent to the head chief, the Sultan of the Ogaden Somalis. It was July 3 before amicable arrangements could be made, and the expedition fairly started. The Somalis met with everywhere were very strict Mohammedans, and secluded their women, but a number of Galla slave-girls were seen amongst them. There were few villages, Hajowan and Hajaualla opposite each other near the mouth being the only large ones until Munaur, 360 miles, and Bardera, 387 miles from the sea, were reached. The lower reaches of the river were very winding. On one occasion Captain Dundas observed a stream flowing parallel to the river he was on, and going across to see it recognized the landmarks as those

he had passed three hours before. The Waboni tribe, who live by hunting, and use the bow and arrow, occupied the thick woods of the lower river. Above them the curves became more gentle, and the Gusha district was reached, where the people cultivated the land, which was cleared by burning, and for a hundred miles the *Kema's* furnaces were fired with the dead trees which had been killed, but left unburnt by the fire. Cotton is cultivated as well as food plants, and there is a primitive system of weaving. Above Bilo, and about 100 miles from the sea, a branch was found to run off from the main river to the south west through very dense forests. This is probably the Sheri, which reaches the sea midway between Lamu and Kisimayu, the land between this and the Juba mouth being probably of deltaic origin. This branch was explored in a boat for twenty miles. The dense forests formed a broad belt on both sides on the river, and after steaming for five days through uninhabited woods the *Kema* suddenly emerged into open country on August 2. The people were of very mixed race, friendly and well supplied with all sorts of food. Hills began to appear, and the river grew shallower, until on August 10 the steamer moored to the bank opposite Bardera. Here the Sultan forbade a landing, and the people, who numbered about 1200, were hostile, but ultimately peace was arranged, and one of the subordinate sheiks accompanied the *Kema* to the rapid, where the river sweeps between steep rocky hills 300 to 400 feet high. There are three channels in the rapids, but at the time of the visit none was navigable, and the natives reported a waterfall over a ledge of rock about four hours' march further up, in latitude  $2^{\circ}34'N$ . The wreck of the *Guelph* was visited and examined, but the rapid falling of the water made it necessary to hasten back to the sea. The climate throughout was found agreeable, and there were few mosquitoes. The river does not overflow, so there are no malarial swamps along the banks.

### BREATH FIGURES<sup>1</sup>

FIFTY years back Prof. Karsten, of Berlin, placed a coin upon glass, and by electrifying it made a latent impression, which revealed itself when breathed upon. About the same time Mr. W. R. (now Sir W. R.) Grove made similar impressions with simple paper devices, and fixed them so as to be always visible. A discussion of Karsten's results occurs in several places, but I have not been able to find details of his method of performing the experiment. During my attempts to repeat it some effects have appeared which seem to be new and worthy of record.

After many trials I found the following method the most successful. — A glass plate, six inches square, is put on the table for insulation. In the middle lies a coin with a strip of tin-foil going from it to the edge of the glass. On this coin lies the glass to be impressed, four or five inches square, and above it a second coin. It is essential to polish the glass scrupulously clean and dry with a leather. The coins may be used just as they usually are, or chemically cleansed, it makes no difference. The tin-foil and the upper coin are connected to the poles of a Wimshurst machine which gives three or four inch sparks. The handle is turned for two minutes, during which one-inch sparks must be kept passing at the poles of the machine. On taking up the glass one can detect no change with the eye or the microscope, but when either side is breathed upon, a clear frosted picture appears of that side of the coin which had faced it. Even a sculptor's mark beneath the head may be read. For convenience those parts where the breath seems to adhere will be called white, the other parts black. In this experiment the more projecting parts of the coin have a black counterpart, but there is a fine gradation of shade to correspond with the depth of cutting in the device; the soft undulations of the head and neck are delicately reproduced.

The microscope shows that moisture is really deposited over the whole surface, the size of the minute water granulation increasing as the point of the picture is darker in shade.

There seems to be no change produced by the use of coins of different metals.

If sparking is allowed across the glass instead of at the poles of the machine, traces of metal are sometimes deposited beyond the disk of the coin, but not within it.

Around the disk is a black ring quarter inch broad. Some times the milling of the coin causes radial lines across this halo.

If carefully protected there appears to be no limit to the permanence of the figures, but commonly they are gradually obscured by the dust gathered up after being often breathed upon. Some of the early ones, done more than two years back, are still clear and well defined in the detail.

It is possible to efface them with some difficulty by rubbing with a leather whilst the glass is moist. They are best preserved by laying several together when dry and wrapping them in paper. They are not blurred by this contact.

It is a curious fact that certain developments take place after a lapse of some weeks or months. The dark ring around the disk gradually changes into a series of three or four, black and white alternately, other instances of such a change will be noted below.

Let it be noticed that in coin pictures the object is near to, but not in contact with, the glass. For in the best specimens the rim of the coin keeps the inner part clear of the surface.

Obviously a small condenser is made by the coins. It is not essential, at the same time images made by a single coin, put to a single pole, are inferior.

The plan which gives the surest and most beautiful results is to place five or six coins, lying in contact side by side in a cross or star, on either side of the glass. It is not necessary that each coin should exactly face one on the other side.

There has not appeared any distinction between the figures made by positive and negative electricity.

When several coins are placed side by side, touching one another, there appear in the spaces between them, which are mostly black, well defined white lines, common tangents to the circular edges of the coins. If these are of equal size the lines are straight, otherwise they are curved, concave towards a smaller coin. They seem to be traces in that plane of the loci of intersection of equipotential surfaces.

Similar effects are obtained when coins and glasses are piled up alternately, and the outer coins are put to the poles of the machine. With six glasses and seven coins perfect images have been formed on both sides of each glass. With eight glasses the figures were imperfect, but there is little doubt this could be improved by continued trials as to the amount of electricity applied.

If several glasses are superposed and coins are applied to the outer surfaces, there are only the two images at the outside. After the electrification there is a strong cohesion between the plates.

It requires some practice to manage the electrification so as to produce the best results. There are two forms of failure which present interesting features. Sometimes a picture comes out with the outlines dotted instead of being continuous. At other times, if the electrification is carried too far, the impression comes out wholly black, but on rubbing the glass when dry with a leather the excess is somehow removed. Naturally it is difficult to rub down exactly to the right point, but I have succeeded on several occasions in developing from a blank all the fine detail of elaborate coins.

Here, again, we have another instance of the development by lapse of time, for an over-excited piece of glass usually gives a clear picture after an interval of a day or two.

Impressions from stereotype plates have been taken of which the greater part is legible. The distinctness usually improves after a few days. In default of a second plate, a piece of tin-foil about the same size should be put on the opposite side of the glass.

Sheet and plate glass of various thicknesses have been used without any noticeable change either in the treatment or the results.

I have put an impressed glass on a photographic plate in the dark, but did not get any result on developing. My imperfect skill in photographic matters leaves this experiment inconclusive.

Probably all polished surfaces may be similarly affected. A plate of quartz gives the most perfect images, which retain their freshness longer than those on glass.

Mica and gelatine give poorer results. It is not possible to polish the surface to the necessary point without scratching it.

On metal surfaces fairly good impressions can be produced if, as Karsten advises, oiled paper is put between the coin and the surface.

In the order of original discovery the figures noticed by Peter Riess should come first. He discusses a breath-track made on

<sup>1</sup> Paper read by Mr. W. B. Croft before the Physical Society of London on June 24, 1892.

glass by a feeble electrical discharge, as well as two permanent marks, noticed by Ettrick, which betray a disintegration of the surface.

I have found that when a stronger discharge is employed more complex phenomena of a similar kind are produced. A six inch Wimshurst machine is arranged with extra condensers, as if to pierce a piece of glass. If this is about four inches square the spark will generally go round it. For a day, more or less, there is only a bleared watery track,  $\frac{1}{8}$  inch wide, when the glass is breathed upon, but after this time others develop themselves within the first, a fine central black line with two white and two black on either side, the total breadth being the original  $\frac{1}{8}$  inch. These breath-lines do not precisely coincide in position with the permanent scars, but the central one is almost the same as a permanent mark, which the microscope shows to be the surface of glass fractured into small squares of considerable regularity: on either side is a grey-blue line always visible, which Riess ascribes to the separation of the polish. After several months I found two blue lines on either side, which I believe were not visible at first. Of course these blue lines may be seen on most Leyden jars, where they have discharged themselves across the glass.

In 1842 Moser, of Königsberg, produced figures on polished surfaces by placing bodies with unequal surfaces near to them, the action was ascribed to the power of light, and his results were compared with those of Daguerre. Moser says, "We cannot therefore doubt that light acts uniformly on all bodies, and that, moreover, all bodies will depict themselves on others, and it only depends on extraneous circumstances whether or not the images become visible." In general, the multitude of images would make confusion, it can only be freshly polished surfaces that are free to reveal single definite impressions. However great Moser's assumption may be, there are many achievements of modern photography that would be as surprising if they were not so familiar. I have not the means of knowing the precise form of Moser's methods in the experiments which follow there is usually contact and light pressure, and if they are not wholly analogous, they may for that cause help to generalize the idea in none of these is electricity applied.

A piece of mica is freshly split, and a coin lightly pressed for thirty seconds on the new surface a breath image of the coin is left behind. At the same time it may be noticed that the breath causes abundant iridescence over the surface, whilst it is in a fresh state. It is not clear how the electricity of cleavage can have an active agency in the result.

It is familiar to most people that a coin resting for a while on glass will give an outline of the disk, and sometimes faint traces of the inner detail when breathed upon.

An examination-paper, printed on one side, is put between two plates of glass and left for ten hours, either in the dark or the daylight. A small weight will keep the paper in continuous contact, but this is not necessary if thick glass is used. A perfect breath impression of the print is made, not only on the glass which lay against the print, but also on that which faced the blank side of the paper. Of course the latter reads directly, and the former inversely, the print was about one year old, and presumably dry.

More often both impressions are white, sometimes one or other or both are black. At other times the same one may be part white and part black, and they even change while being examined.

During a sharp frost with east winds early in March, 1890, these impressions of all kinds were easy to produce, so as to be quite perfect to the last comma, but in general they are difficult, more especially those from the blank side.

At the best period those from the blank side of the paper were white and very strong, also there were white spots and blotches revealed by the breath. They seemed to correspond with slight variations in the structure of the paper, and suggest an idea that the thickness of the ink or paper makes a minute mechanical indentation on the molecules. The state of these is probably tender and sensitive under certain atmospheric conditions, as happens with steel in times of frost.

The following experiments easily succeed at any time. — Stars and crosses of paper are placed for a few hours beneath a plate of glass. Clear white breath-figures of the device will appear. A piece of paper is folded several times each way to form small squares, then spread out and placed under glass. The raised lines of the folds produce white breath-traces, and a letter weight that was above leaves a latent mark of its circular rim.

Some writing is made on paper with ordinary ink and well dried. It will leave a very lasting white breath-image after a few hours' contact. If, with an ivory point, the writing is traced with slight pressure on glass, a black breath image is made at once. Of course this reads directly, and the white one inversely. It is convenient to look through the glass from the other side for inverse impressions, so as to make them read direct.

Plates of glass lie for a few hours on a table-cover worked with sunflowers in silk. They acquire strong white figures from the silk.

In most cases I have warmed the glass, primarily for the sake of cleansing it from moisture, but I have often gone to a heat beyond what this needs, and think that the sensitiveness has been increased thereby.

It is not easy to imagine what leads to the distinction between black and white, different substances act variously in this respect. I have placed various threads for a few hours under a piece of glass, which lay on them with light pressure. Wool gives black, silk white, cotton black, copper white. A twist of tinsel and wool gives a line dotted white and black, after a time these traces show signs of developing into multiple lines as in the spark figures.

Two cases have been reported to me where blinds with embossed letters have left a latent image on the window near which they lay, it was revealed in misty weather, and had not been removed by washing. I have not had a chance to see these for myself, but both my informants were accustomed to scientific observation.

A glass which has lain above a picture for some years, but is kept from contact by the mount, will often show on its inner side an outline of the picture, always visible without breath. It seems to be a dust figure easily removed. Possibly heat and light have loosened fine paint particles, and these have been drawn up to the glass by the electricity made in rubbing the outer side to clean it. The picture must have been well framed and sealed from external influences, most commonly dust and damp get in and obscure such a delicate effect.

I am not able to suggest simple causes for these varied effects. I am not inclined to think, except in the case of water colours, which is hardly part of the enquiry, that there is a definite material deposit or chemical change, one cannot suppose that imperceptible traces of grease, ineradicable as they may be, would produce complete and delicate outlines. The cleaning off of impressions may at first seem to indicate a deposit, but this renewal of the surface might rather be like smoothing out an indented tin-foil surface. Such a view might explain the case where a blank over-electrified disk is developed into fine detail. The electrified figures seem to point to a bombardment, which produces a molecular change, the intensity of electricity bringing about quickly what may also be done by slow persistent action of mechanical pressure. At present it seems as if most of the phenomena cannot be drawn out from the unknown region of molecular agency.

While experimenting I was not within reach of references to former researches, but I have since done my best to find them out, and to indicate all I have learnt in the body of my paper.

## SCIENTIFIC SERIALS

*American Journal of Science*, December. — An experimental comparison of formulæ for total radiation between 15° C. and 110° C., by W. de Conte Stevens. The formulæ given by Dulong and Petit, by Rosetti, Stefan, and Weber, were tested for a comparatively small range of differences by a determination of the heat radiated from an iron disc at a distance of about 30 cm. from a thermopile. The results tended to show that H. F. Weber's formula (*Sitzungsber.*, Berlin, 1888) agrees most closely with experiment. Stefan's formula, according to which the heat emitted in unit of time is proportional to the fourth power of the absolute temperature, is also fairly accurate,

but Dulong and Petit's values are too high, and Rosetti's too low.—Notes on silver, by M. Carey Lea.—Notes on silver chlorides, by the same. Fused silver chloride poured into petroleum and placed in the sunlight without removing it from the liquid, is instantly darkened. From this it appears that the presence of oxygen or moisture is not essential to the darkening of silver chloride in light. The chlorine may be taken up by some other substance.—A remarkable fauna at the base of the Burlington Limestone in north eastern Missouri, by Charles Rollin Keyes.—Glacial pot-holes in California, by H. W. Turner.—The lavas of Mount Ingalls, California, by H. W. Turner.—A method for the quantitative separation of barium from strontium by the action of amyl alcohol on the bromides, by Philip E. Browning. The solubility of barium bromide is about 0.0013 gm. on the oxide in 10 cc. of amyl alcohol, while that of strontium bromide is 0.2 gm. To obtain the bromides, the precipitated and thoroughly washed carbonates of Ba and Sr are treated with hydrobromic acid obtained by the action of dilute sulphuric acid on potassium bromide.—Note on the method for the quantitative separation of strontium from calcium by the action of amyl alcohol on the nitrates, by P. E. Browning. Recent work on this method has shown that the total correction amounts to 0.0006 gm. on the strontium oxide, and 0.0010 on the calcium as sulphate.—Study of the formation of the alloys of tin and iron, with descriptions of some new alloys, by W. P. Headen.—Notes on the Cambrian rocks of Pennsylvania and Maryland from the Susquehanna to the Potomac, by C. D. Walcott.—Volcanic rocks of South Mountain in Pennsylvania and Maryland, by G. H. Williams.

Hallwachs.—On capillary constants, by M. Cantor.—On the chemistry of the accumulator, by M. Cantor.—On the fall of potential during discharges, by O. Lehmann. A series of important investigations on discharges between electrodes and in tubes without electrodes.—Expansion of water with the temperature, by K. Scheel.—A method for determining the density of saturated vapours and the expansion of liquids at higher temperatures, by B. Galitzine. This method has the advantage of extreme simplicity combined with accuracy. A small glass tube, about 5 cm. long and a few mm. thick, is closed at one end and drawn out into a capillary at the other. After determining the weight and internal volume of the tube, a small quantity of the substance to be investigated is introduced into it in the liquid state. This is made to boil, and then the tube is sealed by fusing. On raising the temperature, the surface of separation between the liquid and its vapour is displaced, until at a certain temperature all the liquid is converted into saturated vapour. The tube is then cooled until the vapour reappears, when the temperature is again taken. This can be repeated several times, thus giving an accurate value for the density of saturated vapour at a certain temperature. The same process can be used to determine the expansion of the liquid. As the temperature rises, the volume of the liquid will in general increase up to a certain point, when the vaporization becomes more pronounced. This maximum, which can be observed more accurately by drawing out the tube near that point, gives a value for the expansion. For the density at that point is a function of the density at 0° C. and the temperature, and the pressure is that of the saturated vapour at the same temperature. Thus it is only necessary to find the volumes of the liquid and the vapour, and the density of the latter from the previous experiment.—On radiant energy, by B. Galitzine.—Note on the electricity of waterfalls, by J. Elster and H. Geitel.—Apparatus for demonstrating the Wheatstone bridge arrangement, by A. Oberbeck.—Determination of the coefficient of self-induction by means of the electro dynamometer, by O. Troje.

LONDON.

Royal Society, December 15.—On some new reptiles from the Elgin Sandstone, by E. T. Newton, communicated by Sir Archibald Geikie, F.R.S.

During the last few years a number of reptilian remains have been obtained from the Elgin Sandstone at Cuttle's Hillock,

near Elgin, which are now in the possession of the Elgin Museum and of the Geological Survey. These specimens represent at least eight distinct skeletons, seven of which undoubtedly belong to the *Dicynodontia*, and one is a singular horned reptile, new to science. All the remains yet found in this quarry are in the condition of hollow moulds, the bones themselves having entirely disappeared. In order, therefore, to render the specimens available for study, it was necessary, in the first place, so to display and preserve these cavities that casts might be taken which would reproduce the form of the original bones. Gutta-percha was found to be the most suitable material for taking these impressions, and in some instances, especially in the case of the skulls, the casts had to be made in several parts and afterwards joined together.

The first specimen described is named *Gordonia Traquairi*, it is the one noticed by Dr. Traquair in 1885, and referred to the *Dicynodontia*, besides the skull, it includes fragmentary portions of other parts of the skeleton, and is contained in a block of sandstone which has been split open so as to divide the skull almost vertically and longitudinally. The two halves have been so developed that casts made from them exhibit the left side and upper surface, as well as the main parts of the palate and lower jaw. In general appearance this skull resembles those of *Dicynodon* and *Oudenodon*. The nasal openings are double and directed laterally, the orbits are large and look somewhat forwards and upwards. The supra-temporal fossa is large, and bounded above by the prominent parieto-squamosal crest, and below by the wide supra-temporal bar, which extends downwards posteriorly to form the long pedicle for the articulation of the lower jaw. There is no lower temporal bar. The maxilla is directed downwards and forwards to end in a small tusk. Seen from above, the skull is narrow in the inter-orbital and nasal regions, but wide posteriorly across the temporal bars, although the brain-case itself is very narrow. There is a large pineal fossa in the middle of a spindle-shaped area, which area is formed by a pair of parietals posteriorly and a single intercalary bone anteriorly.

The palate is continuous with the base of the skull, the pterygoids on each side send off a distinct process to the quadrate region. Towards the front the median part of the united pterygoids arches upwards, and the outer sides descend, forming a deep groove, from the evidence of other specimens it is clear that the palatines, extending inwards, converted this groove into a tube, and thus formed the posterior nares. The ramus of the lower jaw is deep, with a large lateral vacuity, and the two rami are completely united at the symphysis. The back of this skull is not seen, but two other specimens, referable to this same genus, show that the occiput had two post-temporal fossae on each side.

This specimen is distinguished from *Dicynodon* by the presence of two post-temporal fossae on each side of the occiput, by the small size of the maxillary tusk, and probably by the elongated spindle-shaped area enclosing the pineal fossa, and also by the slight ossification of the vertebral centra.

A second and much smaller specimen, provisionally referred to *G. Traquairi*, has, besides the skull, a fore-limb well preserved. The humerus of this shows the usual *Anomodont* expansion of its extremities, its large deltoid crest is angular, and set obliquely to the distal end.

Three other species are referred to the same genus, namely—*Gordonia Huxleyana*, which is distinguished from *G. Traquairi* by its proportionately wider and more depressed skull, and by the absence of the concavity between the orbits which is present in the latter species. The humerus has the distal extremity oblique to the deltoid crest, which was probably rounded and not angular.

*G. Duffiana* has the skull even wider than in *G. Huxleyana*, and the portion of a humerus found with this skeleton has the two extremities set nearly at right angles to each other.

*G. Juddiana* has an elongated skull resembling that of *G. Traquairi*, but the parietal crests are less developed, the bones of the nasal region are much thickened and overlap the nasal apertures, the small tusk is placed a little further back and points more directly downwards, and the pineal fossa is smaller than in either of the other species.

A second generic form is named *Griksa Elginensis*. This is a skull nearly allied to *Ptychognathus*, Owen, but is distinguished by its shorter muzzle and the entire absence of teeth, the upper part of the skull, between the orbits, is also peculiar, forming a deep valley open anteriorly, with a ridge on each side, the anterior

end of which forms a large prominence above and in front of the orbit. The occiput has only one (the lower) post-temporal fossa open on each side. The maxilla is produced into a tooth like prominence, which occupies a similar position to the tusks of *Gordonia*, but the bone is too thin to have supported a tooth, and in all probability it was covered by a horny beak. The lower jaw has a strong symphysis, a distinct lateral vacuity, and the oral margin, at the foot of each ramus, bears a rugose prominence.

*Elginia mirabilis* is the name proposed for the skull of a reptile, which, on account of the extreme development of horns and spines, reminds one of the living lizards *Moloch* and *Phrynosoma*. The exterior of this skull is covered in by bony plates, the only apertures being the pair of nostrils, the orbits, and the pineal fossa. The surfaces of the bones are deeply pitted, as in crocodiles and labyrinthodonts. The horns and spines, which vary from  $\frac{1}{2}$  in to nearly 3 in in length, are found upon nearly every bone of the exterior. The development of the epiotics, and the arrangement of the external bones, resemble more the Labyrinthodont than the reptilian type of structure, while the palate, on the other hand, conforms more nearly to the Lacertilian type, and, with the exception that the pterygoids are united in front of the pterygoid vacuity, agrees with the palate of *Iguan* and *Sphenodon*. There are four longitudinal ridges along the palate, some of which seem to have carried teeth. The oral margin was armed with a pleurodont dentition, there being on each side about twelve teeth with spatulate crowns, laterally compressed and serrated. With the exception of the smaller number of the teeth, we have here, on a large scale, a repetition of the dentition of *Iguana*. This peculiar skull seems to show affinities with both Labyrinthodonts and Lacertilians, and is unlike any living or fossil form, its nearest, though distant, ally apparently being the *Pariasaurus* from the Karoo beds of South Africa.

Linnean Society, December 1.—Prof. Stewart, President, in the chair.—A letter was read from the Rev. Leonard Blomefield, expressing his high appreciation of the compliment paid him by the presentation of the illuminated address which had been signed by the Fellows present at the last meeting of the Society and forwarded to him.—Messrs. H. and J. Groves exhibited specimens of several Irish *Characea* collected during the past summer. *Nitella tenuissima* from Westmeath and Galway had not been previously recorded from Ireland, and a large form of *N. gracilis* from two lakes in Wicklow had been only once previously met with. Referring to the former, Mr. H. Groves remarked that although it might be expected to occur in all the peat districts it had only been found in two widely separated localities in England, namely, in the Cambridgeshire Fens and in Anglesea.—Mr. A. Lister made some remarks on the nuclei of Mycetozoa, exhibiting some preparations under the microscope.—Mr. E. Cambridge Phillips forwarded for exhibition a hybrid between red and black grouse, which had been shot in August near Brecon.—Mr. J. E. Harting exhibited and made remarks on some coleopterous larvæ which had been vomited by a child at Tintern, and had been forwarded by the medical attendant, Dr. J. Taylor Brown, for identification. The precise species had not been determined, but was considered to be allied to *Blaps mortisaga*. Mr. Harting drew attention to the fact that cases of voiding coleopterous larvæ were mentioned by Kirby and Spence (7th ed. p. 71), and by the late Dr. Spencer Cobbold in his work on parasites (1879, p. 269).—Mr. D. Morris exhibited some tubers of *Calathia allouia*, eaten as potatoes in Trinidad, where it is known as Tapee Nambour. Apparently a corruption from the French *topinambour* (artichoke).—A communication was read from Mr. J. H. Hart, of the Botanic Gardens, Trinidad, on *Ecodoma cephalotes* and the fungi it cultivates.—Prof. F. Jeffry Bell contributed a short paper on a small collection of Crinoids from the Sahul Bank, North Australia, some of which were new, and Mr. Edgar Smith communicated descriptions of some new land shells from Borneo.—The meeting adjourned to December 15.

Physical Society, December 9.—Mr. Walter Baily, Vice-President, in the chair.—The Chairman announced that an extra meeting would be held on January 13, 1893.—Prof. S. P. Thompson's communication on Japanese magic mirrors was postponed.—Mr. W. B. Croft read a paper on the spectra of various orders of colours in Newton's scale. After referring to the definition of the order of colours by reference to the retardation in wave-lengths, produced by different thicknesses of selenite

between crossed polarizer and analyzer, the author went on to say that several books on optics implied that the number of bands in the spectra of these colours was the same as the order of the colour. On obtaining selenites of the first four orders of red from Messrs. Steeg and Reuter, he found that the first three orders gave one dark band each, and that of the fourth order three dark bands. Further experiments showed that the thicknesses of the selenites were in the proper proportions required to give the first four orders of red. The numbers of bands, the author explained, depended on the numerical possibilities of wave-length within the visible spectrum—that is, whether a multiple of the wave-length of one visible wave can be another multiple of a different wave. For example, taking the visible spectrum as extending from A (0.000760) to H (0.000394) and the wave-length of the line E in the green as 0.000527, it was shown that the first order of red was due to extinction of green by a thickness of crystal proportional to  $1 \times 0.000527$ , and would give one band in the green. For the second order, the thickness of crystal was proportional to  $2 \times 0.000527$ , viz. 0.001054, and this number was no other integral multiple of any other wave-length between A and H, consequently there could only be one band. Similarly it was shown that the third order of red could only have one band or possibly produce a shortening of the spectrum. With the fourth order of red three bands were obtainable, for  $4 \times 0.000527 = 3 \times 0.000703$  and  $= 5 \times 0.000422$ . Three bands were therefore possible near F, A, G, respectively. At the conclusion of his paper, Mr. Croft directed attention to a very simple form of diffraction apparatus, by which most of the ordinary diffraction phenomena could be well seen, and which also served for spectrum observations. Mr. H. Miers pointed out that in Lewis Wright's "Practical Optics" a chart showing the bands corresponding to the first four orders of red was given. So far as he was aware, the subject was not fully discussed in the book. In reply, Mr. Croft said he had noticed Mr. Wright's chart, but believed the text implied that the number of bands should be the same as the order of the colour. Tyndall made definite statements to that effect.—Dr. W. E. Sumner read a paper on the diffusion of light. The influence of diffusion in increasing the illumination of rooms and open spaces, had not, in the author's opinion, been sufficiently appreciated. Being impressed with the great importance of the subject, he was led to make determinations of the coefficients of reflection, absorption, and transmission of diffusing surfaces. To give precision to terms sometimes vaguely used, several definitions were proposed. *Reflecting power* was defined as the ratio of the amount of light reflected from a surface to the total amount of light incident upon it, *illumination* of a surface, as the amount of incident light per unit of surface, *unit quantity* of light as the flux of radiation across unit area of a sphere of unit radius at whose centre a unit light is placed, and *brightness* as the candle-power per unit area in the direction normal to the surface. Denoting these quantities by  $\eta$ ,  $I$ ,  $Q$  and  $B$  respectively, and assuming the cosine law of diffusion (i.e. the candle-power in any direction is proportional to the cosine of the angle between the direction and the normal to the surface) it was shown that  $\pi B = \eta I$ , and that the average illumination ( $I'$ ) of the walls of a room is related to the illumination ( $I$ ) due to the direct action of the lights as expressed by the formula  $I' = \frac{I}{1 - \eta}$ . If the re-

fecting power of the walls, &c., be 50 per cent,  $\eta = \frac{1}{2}$ , and  $I' = 2I$ , whilst if  $\eta = 0.8$ , a number approximately true for white surfaces, then  $I' = 5I$ . The illumination due to the walls may, therefore, be far more important than that due to the direct rays from the lights. When the surfaces consist of portions of different reflecting power, the average reflecting power may be found

from the equation  $\eta = \frac{\eta_1 A_1 + \eta_2 A_2 + \&c.}{A}$ , A being the total

surface, and  $A_1$ ,  $A_2$ , &c., the areas of surfaces whose reflecting powers are  $\eta_1$ ,  $\eta_2$ , &c., respectively. This law is shown to be quite accurate for spherical enclosures. In measuring reflecting power, the surface was attached to a large screen of black velvet placed perpendicular to a 3 metre photometer bench. Two lights were used, one a Methven 2-candle standard placed at the end of the bench remote from the reflecting surface, and the other, a glow lamp of about 20 candle power, was attached to a slider which also carried a Lummer-Brodhun photometer. The glow lamp served to illuminate the reflecting surface, but the photometer was screened from its direct rays. The formulae used in reducing the observations are worked out in the paper.

and tables of results given. Absorbing power was determined by measuring the candle-power of a glow lamp, first when uncovered, and then when surrounded by a cylinder of the substance under test. It was found to be of great importance to distinguish between apparent and real absorption, for reflection from the surfaces of the cylinders increases the internal illumination. The true absorption coefficient ( $\alpha$ ) is given by  $\alpha = (1 - \eta) \frac{k_0 - k_1}{k_0}$ , where  $\eta$  is the reflecting power and  $k_1$  and  $k_0$  the candle-powers with and without the envelope of material under test. In determining transmitting power, the Methven standard and photometer were placed on one side of the surface and the glow lamp on the other. Difficulties were experienced from the fact that some materials such as tracing paper, translucent part of the light directly (like transparent substances), and another part by diffusions according to the cosine law. Methods for discriminating between the different parts were therefore devised both in the reflection and transmission experiments, and consistent results subsequently obtained. Tables and curves showing the close agreement of calculated and observed values, are included in the paper. An abstract of some of the tables of numbers is given below —

Material	Percentage reflecting power $\eta$	Percentage absorption $\alpha$	Percentage Transmission $\tau$	$\eta + \alpha + \tau$
Blotting paper	82	13.8	9.2	105.0
Cartilage paper	80	12.2	11.2	103.4
Tracing cloth	35	15.0	54.4	104.4
Tracing paper	22	7.0	76.0	105.0
Ordinary mirror	82			
Ordinary fool-cap	50 to 70			
Tissue paper (one thickness)	40			
Tissue paper (two thicknesses)	55			
Yellow wall-paper	40			
Blue paper	25			
Dark brown paper	13			
Yellow painted wall	20			
Black cloth	12			
Black velvet	0.4	(apparent)		
Arc lamp globes—				
Light opal	—	15		
Dense opal	—	39		
Ground glass	—	42		

Theoretically the sum of the reflecting, absorbing and transmitting powers should be unity, but from the above table it will be noticed that they exceed 100 per cent., by amounts greater than can be accounted for by experimental error. This discrepancy, the author thought, might be attributed to the law of cosines not being exactly fulfilled. Mr. A. P. Trotter said he had been interested in the subject of diffusion for many years with a view to obviating the glare of arc lamps. Some experiments he made on reflecting power gave unsatisfactory results, owing, as he now saw, to his not taking the solid angles subtended by the reflecting surfaces into account. The reflecting power of substances was of great importance in the illumination of rooms, in one case measured by Dr. Sumpner and himself, two thirds of the total illumination was due to the walls. It would greatly simplify measurement of reflecting power if some substance could be adopted as a standard. Referring to the cosine law, he said he had found it true, except when the angles of incidence approached 90°. In cases where considerable total reflection took place the apparent brightness near the normal direction was greatly in excess of that in other directions. These points he illustrated by polar curves. He had also considered what should be the nature of a roughened or grooved surface to give the cosine law of diffusion. No simple geometrical form of corrugations, &c., seemed to fulfil the required conditions. Dr. Hoffer said the high numbers given for the reflecting powers of substances were very interesting. Most people had noticed the effect of laying a white table cloth in an ordinary room. He had also observed that wall papers of the

same pattern, but slightly different in colour, had very different effects in producing increased illumination, and wished to know if the influence of small differences in colour and texture on diffusing power, had been investigated. Mr. Blakesley defended the cosine law, and suggested that the summation of the powers exceeding unity might be due to the fact that the enclosure reflected heat as well as light, thus raising the temperature and increasing the efficiency of the radiant. Mr. Addenbrooke said the importance of the subject was impressed on him when he passed through America three years ago and noticed the crude manner in which electric lighting was there carried out. If using good reflecting surfaces increased the illumination of a room 50 per cent., it was like reducing the cost of electricity from 8d to 4d per unit. He could hardly conceive any subject of more practical importance than the one before the meeting. Dr. C. V. Burton did not understand why the cosine law should be objected to, for it was possible that no surface was perfectly diffusive. The effect of reflection from walls, &c., say in illuminating a book would not, he thought, be so great as would appear from the numbers given, for one usually read near a light, and the reflected light falling on the book was only a small part of the whole, on account of the greater distances of the walls. Another member pointed out that in experiments such as those described, it was very important to screen the photometer and surfaces from all radiation other than that under test. He rather doubted whether any surface reflected as well as mirrors. White surfaces might appear to do so, but this was probably because the eye would overestimate it, owing to the superiority of white in aiding distinct vision. Dr. Sumpner in reply said he had, as stated in the paper, used white blotting paper as a standard of reflecting power and found it very convenient. His most careful measurements had been made on whitish surfaces and not on coloured ones. Where one colour, say red, preponderates in a room, the average light would be much redder than that emitted by the source owing to the other colours being absorbed. In considering illumination as related to distinct vision, it was necessary to take account of the eye itself, for the pupil contracted in strong lights and opened in feeble ones. This subject he hoped to treat fully in a subsequent paper.

Entomological Society, December 7 — Frederick DuCane Godman, F.R.S., President, in the chair — The President announced the death, on December 2, of Mr. Henry T. Stainton, F.R.S., an ex-President and ex-Secretary of the Society. Mr. Jenner Weir exhibited a species of *Acinea* from Sierra Leone, which Mr. Roland Trimen, F.R.S., who had examined the specimen, considered to be a remarkable variety of *Telechma encelon*, Linn. It was a very close mimic of *Limnas aliphus*, the usual West African form of *Limnas chrysippus*. The upper wings of the specimen were rufous and the lower white, as in the model, and the resemblance in other respects was heightened by the almost total suppression of the black spots in the disc of the upper wings, characteristic of the usual markings of *T. encelon*. — Mr. F. J. Hanbury exhibited a remarkable variety of *Lycena adonis*, caught in Kent this year, with only one large spot on the under side of each upper wing, and the spots on the lower wings entirely replaced by suffused white patches. He also exhibited two specimens of *Noctua xanthographa* of a remarkably pale brownish grey colour, approaching a dirty white, obtained in Essex, in 1891, and a variety of *Acronycta rumex*, also taken in Essex, with a dark hind margin to the fore wings. — Mr. H. J. Elwes exhibited a living specimen of a species of *Conocephalus*, a genus of *Locustidae*, several species of which, Mr. McLachlan stated, had been found alive in hothouses in this country. — Dr. T. A. Chapman exhibited immature specimens of *Tamocampa gracilis*, *T. gohuca*, *T. populeti*, *T. munda*, *T. instabilis* and *T. leucographa*, which had been taken out of their cocoons in the autumn, with the object of showing the then state of development of the imago. — Mr. F. W. Frohawk exhibited a living specimen of the larva of *Cartrocephalus palemon* (*Hesperia paniscus*) hibernating on a species of grass which he believed to be *Bromus asper*. The Rev. Canon Fowler and Mr. H. Goss expressed their interest at seeing the larva of this local species, the imago of which they had respectively collected in certain woods in Lincolnshire and Northamptonshire. Mr. Goss stated that the food-plants of the species were supposed to be *Plantago major* and *Cynosurus cristatus*, but that the larva might possibly feed on *Bromus asper*. — Mr. C. G. Barrett exhibited a long series of remarkable melanic varieties of *Boarmia repandata*, bred

by Mr A E Hall from larvæ collected near Sheffield — Mr W Farren exhibited four varieties of *Papilio machaon* from Wicken Fen, also a series of two or three species of *Nepticula* pinned on pith with the "minutien Nadeln," for the purpose of showing these pins — Canon Fowler exhibited specimens of *Xyleborus perforans*, Woll which had been devastating the sugar canes in the West Indies — Mr E B Poulton, F.R.S., showed, by means of the oxy-hydrogen lantern, slides of various larvæ and pupæ, in illustration of his paper, read at the October meeting, entitled, "Further experiments upon the colour-relation between certain lepidopterous larvæ and their surroundings." He stated that he believed that nineteen out of twenty larvæ of *Geometridæ* possessed the power of colour adjustment — Mr F Merrifield, the Rev J Seymour St John, and Mr Jacoby took part in the discussion which ensued — Mr F. Merrifield read a paper entitled, "The effects of temperature on the colouring of *Pieris napi*, *Vanessa atalanta*, *Chrysophanus phlaas* and *Ephyra punctata*," and exhibited many specimens thus affected — Mr Poulton, Dr F A Dixey, Mr. Elwes, and Mr Jenner Weir took part in the discussion which ensued — Mr Kenneth J Morton communicated a paper entitled, "Notes on *Hydroptilidæ* belonging to the European Fauna, with descriptions of new species" — Dr T A Chapman read a paper entitled, "On some neglected points in the structure of the pupa of Heterocerous Lepidoptera, and their probable value in classification, with some associated observations on larval prolegs." Mr Poulton, Mr Tutt, Mr Hampson, and Mr Gahan took part in the discussion which ensued — Mr J Cosmo-Mellivill communicated a paper entitled, "Description of a new species of butterfly of the genus *Calinaga*, from Siam" — Mr W L Distant communicated a paper entitled, "Descriptions of new genera and species of Neotropical *Rhynchota*."

## PARIS.

Academy of Sciences, December 12. — M d'Abbadie in the chair — On certain asymptotic solutions of differential equations, by M Emile Picard — Description of a new electric furnace, by M Henri Moissan. The furnace consists of two bricks of quicklime one upon the other, the lower one of which is provided with a longitudinal groove which carries the two electrodes, and between them is a small cavity serving as crucible, which contains a layer of several centimetres of the substance to be experimented upon. The latter may also be contained in a small carbon crucible. The highest temperature worked with was 3000° C, produced by a current of 450 amperes and 70 volts consuming 50 horse power. In the neighbourhood of 2500°, lime, strontia and magnesia crystallized in a few minutes. At 3000° the quicklime composing the furnace began to run like water. At the same temperature the carbon rapidly reduced the oxide of calcium to the metallic state. The oxides of nickel, cobalt, manganese, and chromium were reduced in a few seconds at 2500°, and a button of uranium weighing 120 gr was obtained from the oxide in ten minutes at 3000° — Action of a high temperature on metallic oxides, by M Henri Moissan. In all the experiments, the simple elevation of temperature produced the crystallization of all the metallic oxides experimented upon — On the existence of the diamond in meteoric iron of the Cañon Diablo, by M. C Friedel. A careful analysis has placed beyond doubt the existence of diamond in a portion of the Arizona meteorite presented to the Ecole des Mines. It occurs in small grains or a fine powder disseminated through the iron. — On the laws of expansion of fluids at constant volume, coefficients of pressure, by E H Amagat — On the means of diminishing the pathogenic power of fermented beet-root pulp, by M Arlong — On the employment of free balloons for meteorological observations at very great heights, by M Ch Renard — Photographic observations of Holmes' comet, by M H Deslandres — On the locus of the mean distances of a point of an ordinary epicycloid, and of the successive centres of curvature which correspond to it, by M G Foutet — On ordinary linear differential equations, by M. Jules Cels — On the common cause of the evaporation and surface tension of liquids, by M G van der Mensbrugghe — On the relation between the velocity of light and the size of the molecules of refracting liquids, by M P Joubin. From a comparison of a large number of substances the following law is deduced. The refraction is proportional to the square root of the quotient of the weight of the molecule by the number of constituent atoms (mean weight of the atom). — On the anomalous propagation of the light waves of Newton's rings, by M Ch. ## GORE'S "VISIBLE UNIVERSE"

*The Visible Universe* By J Ellard Gore, FRAS  
(London Crosby Lockwood and Son, 1893)

THE object of this book is "not to propound any new hypothesis, but simply to explain and discuss theories which have been supported by well-known astronomers and other men of science" as to the "evolution of the Solar System," and to give a popular account of the "construction of the Universe *as we see it*, and its probable development from pre-existent matter."

Mr Gore has already acquired considerable success as a popular writer on astronomical subjects, and the scheme of the present volume is, as we might expect, a very good one. The first three chapters are devoted to a popular account of the hypotheses of Kant and Laplace, the principal objections that have been urged against them, and the modifications and additions suggested by recent research. In subsequent chapters such subjects as the fuel of the sun, the luminiferous ether, the constitution of matter, celestial chemistry, and the meteoritic hypothesis are dealt with. Mr Gore then reaches the purely descriptive portion of his subject, and gives excellent chapters on the Milky Way, and on "the latest results respecting the distribution of stars and nebulae and their relative motions." Various theories of the construction of the Universe are then discussed, and in a final chapter the idea of infinite space and a finite universe is developed.

Although the general scheme of the book is excellent, the execution falls in many places far short of its promise and our expectations. When Mr Gore confines himself to the historical and descriptive his work is, on the whole, well done, but in discussing theories he has in several cases obviously ventured out of his depth, and has consequently spoiled what would otherwise have been a valuable addition to popular astronomical literature.

For his chapters on the Nebular Hypothesis and Faye's theory of the formation of the solar system Mr Gore has largely availed himself of M Wolf's "*Les Hypothèses Cosmogoniques*." He has also introduced extensive quotations from "the late Mr Jacob Ennis," but in considering Ennis as an authority, Mr Gore is probably alone. Mr Ennis was, on his own admission, not a mathematician, and certainly did not by "his own discoveries," place the nebular hypothesis on a firm mathematical basis. He proved Mars could not have satellites; that the heat of the sun was entirely due to chemical combination; that Sirius has twelve planetary attendants, and made several other equally important discoveries. His mathematical demonstration of the truth of the nebular hypothesis is about as sound as the well-known proofs that the earth's surface is flat. Mr Gore would have done well to have omitted the quotations from Ennis, and to have filled the space with a fuller account of the recent mathematical investigations of the nebular hypothesis, especially those of Prof. G. H. Darwin.

Quoting freely from Young and Sir William Thomson, Mr Gore is fairly safe in his chapter on the fuel of the sun, but he is in error in stating that "the

meteoric theory of the sun's heat must be abandoned." It is true that the larger portion of the solar heat is believed to be due to shrinkage, but it is generally conceded that a considerable fraction has its origin in falls of meteoric matter into the sun. A glaring case of the misuse of a scientific term occurs in this chapter (p 52), where Mr Gore is responsible for the statement that "the theory generally held by astronomers ascribes the heat of the sun to shrinkage of its *mass* caused by gravitation." Mr Gore surely meant *volume*.

The chapter on celestial chemistry is meagre and unsatisfactory. It seems incredible that the application of photography to spectroscopic work is not even mentioned, and that no allusion is made to the Draper catalogue of photographic stellar spectra, to Rowland's photographic map of the solar spectrum, or to any of the recent photographic work. Mr Gore is also in error in this chapter when he states (p 79) that although the great nebula in Andromeda "has never been resolved into stars the evidence of the spectroscope shows it is not gaseous." Bright bands have been seen in the spectrum by Backhouse, Fowler, and myself, and these have been identified as probably due to carbon radiation.

The Meteoritic Hypothesis is dealt with in considerable detail, and here Mr Gore is most seriously in error. He gives what is professedly "a review of the principal facts and arguments advanced by Lockyer," and carefully enumerates all the objections that have been urged by "his opponents," ending the account with the opinion that "on the whole, therefore, we seem bound to conclude that the weight of evidence is against the truth of the Meteoritic Hypothesis." The chapter bears internal evidence that Mr Gore began his consideration of this hypothesis with the opinion which he enunciates as his final judgment, already formed.

The summary of Prof Lockyer's book has not been made with the care that should have been bestowed upon it. There are at least two misquotations, on p 91, the substitution of "periastron" for "perihelion" makes nonsense of what is otherwise an important paragraph, and on p 113 the omission of the word "other" considerably modifies the meaning of the passage quoted.

There are several errors due to hasty compilation, observations and theories being attributed to Prof Lockyer in cases where he only quotes the observations and adopts the theories. On p 92 Mr Gore says "he (Lockyer) also finds line absorption in Comet Wells and the great September comet of 1882." This is misleading, the observations of absorption having been made by Copeland, Maunder, and Vogel. On p 93 we find the "theory that the light of comets is due to collisions between the component meteorites" attributed to Prof Lockyer. The theory is due to Reichenbach, Frit, and Sir William Thomson, Prof Lockyer's contribution being the demonstration that spectroscopic observations lead to and support the hypothesis. The results of Frit's calculations given on pp. 227-229 of the "*Meteoritic Hypothesis*" are also attributed to Lockyer on p 93 of Mr Gore's book. On p 95 we read, "the spectra of the true nebulae consist of a very faint continuous spectrum crossed by one, two, three, or four bright lines." Lockyer gives seventeen bright lines in his table. Mr Gore's footnote that "the complete hydrogen series of lines were

K

photographed by Dr Huggins in 1890," in the great nebula in Orion is also a mistake

Mr Gore has evidently failed to appreciate the importance of several portions of Prof Lockyer's book, and has consequently omitted to mention them in his summary. Thus the observations of meteoritic glows recorded on pp 49-51 of the "Meteoritic Hypothesis" are entirely passed over. In these experiments it was found that on slowly warming meteorites in a vacuum tube through which electric discharges were passing, the spectrum of hydrogen was first developed, then carbon was added, and the first line due to any metal was the 500 line which is the characteristic nebular line. Further heating gave the 495 line and then the B magnesium lines. These experiments, omitted in Mr Gore's summary, are an effective answer to the objections of Messrs Liveing and Dewar given on p. 116 of this book, for we have here the 500 line developed in presence of hydrogen, and at a lower temperature than the B lines.

Mr. Gore believes that "one of the crucial tests of the meteoritic hypothesis" is the question of the identity of the 500 nebular line with the magnesium fluting at this wave-length. He says (p 86) that "it is on the identity of this fluting (or rather its brightest edge) with the chief line in the spectrum of the nebula that the meteoritic hypothesis mainly depends," and from pp 118-121 it is obvious that he thinks the evidence conclusively against the hypothesis on this point.

In the first case the identity of the 500 nebular line with magnesium is not essential to the meteoritic hypothesis, although the latest observations have strongly supported the case for the identity. The main point is whether the 500 nebular line is due to high or to low temperature, and whether nebulae are high or low temperature phenomena. Previous to the publication of Prof Lockyer's book all cosmical bodies were believed to be cooling. The nebulae were considered to be the hottest of all bodies, and on losing heat were supposed to pass into stars of the Sirian type. Further loss of heat converted them into stars of the solar type, and by still further loss they became red stars with banded spectra before reaching final extinction. This hypothesis was supplemented by Dr Croll, who suggested that nebulae were formed by the complete and almost instantaneous volatilisation of these dark bodies on collision, the heat generated by impact being sufficient for the purpose. Lockyer's hypothesis supposes nebulae to be loose swarms of colliding meteorites. Condensation of these swarms by gravitation increases the number of collisions, and as the temperature rises we get stars with bright lines in their spectra. Further increase of temperature gives red stars of Secchi's III class, which pass with still rising temperature into stars with fine absorption lines in their spectra, and so on until the Sirian type is reached, in which we have the highest temperature. Collisions have now ceased and the process of cooling begins, the stars passing into the solar type, then into red stars of Secchi's IV class, and to final extinction.

The lines in the spectra of nebulae and bright line stars according to this theory may be due to three causes: (a) Radiating vapours filling the inter-spaces between the meteorites; the lines of hydrogen and the bands of

carbon being due to these. (b) Low temperature lines of metals, due to grazing collisions of meteorites. (c) High temperature lines of metals, due to direct collisions. It is essential to the theory that low temperature lines of metals should be found in nebulae spectra, and the low temperature origin of the 500 line seems clearly established. Its chemical origin is of quite secondary importance. That it is due to low temperature is shown by the experiments on meteoritic glows which Mr Gore omits, by its presence in comets away from the sun, as observed by Huggins in 1866 and 1867 (this being the only line present), by Vogel in Coggia's comet, and Konkoly in the great September comet of 1882, and also by the fact that it persists in all temporary stars as the temperature falls and is the last line to disappear. Until these facts are explained away the foundation of the meteoritic hypothesis remains unshaken. Mr Gore seems unaware that this main point is now generally admitted, for although the low temperature origin of nebulae was denied by Dr Huggins as late as 1889, it was adopted in his Address to the British Association at Cardiff in 1892.

There is early evidence in the book that Mr Gore has entirely failed to grasp this essential point of the hypothesis. On p 41, discussing Croll's impact theory of the formation of nebulae, he says, "according to Prof Lockyer the temperature of the original solar nebula was as high as that of the sun at present." Mr Gore would have done well to have noted that on p 528 of his book Prof Lockyer explicitly states that "the temperature of the most prominent radiating vapours in nebulae is about that of the Bunsen burner."

Mr. Gore's misconception of the theory and the spirit in which he approached its discussion are also shown on p 101, where he says, "All these conclusions rest, of course, on the supposed coincidence of certain lines in the spectra of comets, nebulae, and stars, with bright lines and flutings, a coincidence which has been disputed by other observers. Relying, however, on the accuracy of his experiments, Lockyer proposes a new grouping of cosmical bodies. He supposes some of these bodies to be increasing in temperature, while others—like our own sun—are cooling." To this he adds a footnote, "Lockyer's curve rests on this assumption, but it should be stated that some astronomers doubt that the sun is really cooling." We should be glad to know who these "astronomers" are. Mr Gore himself is evidently not of their number, for he distinctly recognizes the sun as a cooling body in his chapter on the fuel of the sun, and specially mentions it as such on pp 42 and 53. It is possible that Mr Gore has misunderstood the apparently paradoxical fact that a body, in changing from a gas to a liquid, may rise in temperature while losing heat, but that will not justify the loose style which leaves it to be understood by the general reader that Lockyer's curve rests solely on his experiments, and the "assumption" that the sun is cooling, and that this fact is doubted by some astronomers. We are quite aware that Mr Gore's expression will bear other interpretations, but this is the idea conveyed to several readers to whom we have shown the book.

Returning to the question of the coincidence of the 500 nebular line with magnesium, the evidence recorded by Mr Gore is in favour of, rather than against, the identity.

His facts are — Huggins finds the wave-length in the Orion nebula as 5004.75, the magnesium fluting being 5006.5, a difference of 1.75. At the same time, Huggins finds very little, if any, sensible motion in the line of sight. Mr Keeler finds as a mean from 10 nebulae 5005.68, magnesium being, according to his measurement, 5006.36, a difference of 68. These latter observations completely invalidate Huggins's evidence on this point, especially as Mr Keeler recognizes a motion of recession for the Orion nebula of 10.7 miles per second.

Mr Gore ought to have recorded the fact that in Keeler's observations the comparisons for different nebulae gave the magnesium sometimes more refrangible and sometimes less refrangible than the nebular line. Later observations of Keeler, "corrected for the earth's orbital motion and the sun's motion," give the nebular line a wave-length of 5005.93, *i.e.* only .43 from the magnesium. Assuming Keeler's latest results as perfectly correct, and placing his position at Charing Cross, while representing the position found for this line by Dr Huggins in 1868 at St Paul's Cathedral, we find Dr Huggins's limiting positions in 1889 as the extreme east and extreme west ends of Green Park, his 1890 position in the middle of Green Park, while the magnesium fluting will be at Cecil Street. When we consider that a motion in the line of sight of less than twenty miles per second will make the nebular line and the magnesium fluting absolutely coincident, that the rate of the sun's motion in space is estimated but not absolutely known, that these measurements are probably the most difficult of all astronomical observations, and that every increase of power and accuracy has brought the lines closer together, we are certainly *not* justified in stating that the "weight of evidence" is "against the truth of the hypothesis." The differences in recorded wave-lengths of well-known solar lines by experienced observers are in many cases greater than the difference in question here.

Mr Gore regards the dispersion used by Prof Lockyer as insufficient, and yet he records that sixteen prisms were used by Lockyer in some of his observations of the coincidence of the nebular line with magnesium, so that his dispersion was actually greater than that used by Dr Huggins, and two-thirds that of Mr Keeler, whose dispersion equalled twenty-four prisms.

The objections to that portion of the meteoritic hypothesis which deals with the meteoritic origin of the lines in the auroral spectrum do not in any way affect the main hypothesis. That this subject is unimportant is distinctly recognized by Prof Lockyer, "Meteoritic Hypothesis," p. 97, where he claims that "certainly the coincidence is such as to justify us in regarding meteoritic dust as the origin of the spectrum until a better and more probable origin is demonstrated."

We are told (p. 122) that Mr Monck objects to Lockyer's hypothesis, because it contains no explanation of "why all the planets and asteroids and the great majority of the satellites revolve in the same direction, why the orbits of the larger bodies of the system deviate so little from the circle and why they are so nearly in the same plane." This was asked in 1890, and yet Prof G. H. Darwin had in 1888 shown that a swarm of meteorites which, on the meteoritic hypothesis would form a nebula,

may be considered as a gas, and therefore any answer that the nebular hypothesis can give to these questions will also apply to the meteoritic hypothesis.

Such puerile suggestions as that the meteorites used by Prof Lockyer "*may have been*" of terrestrial origin — "that meteor clouds dense enough to produce the requisite amount of light by their collisions would also be dense enough to intercept *a great part of it* again on its way to the earth" (the italics are ours); and objections based on Mr Monck's interpretation of Prof Newton's calculations, and on opinions to which Mr Monck "*inclines*" as to the origin of certain comets, are evidence that Mr Gore has not hesitated to avail himself of anything that in any way seems to disagree with the meteoritic hypothesis. The whole of the "objections" of the "opponents" of Prof Lockyer recorded by Mr Gore are on matters of secondary importance, and have been insisted upon by him owing to his complete misconception of the theory. As a guide to the meteoritic hypothesis his chapter is misleading, and utterly valueless either as exposition or as criticism.

After his account of the meteoritic hypothesis Mr Gore abruptly turns to a comparison of the various drawings that have been made of the Milky Way, and gives an interesting and valuable summary of the present state of our knowledge as to star distribution and movement and the construction of the Universe. For this portion of the book we have nothing but praise. It is carefully written and copiously illustrated. Mr Gore has evidently taken the word "visible" in its widest possible sense, for he includes not only things visible to the retina of the eye, but those visible to the retina of the camera, and six excellent reproductions of photographs of nebulae and stars clearly demonstrate the superiority of the latter for astronomical purposes. It is probable that the use of photography in the preparation of complete charts of the Milky Way will throw much new light upon many of the points discussed in this portion of the book, and may profoundly modify many of the views at present held, but in presenting a clear and concise account of the present state of our knowledge Mr Gore has made a valuable addition to the literature of the subject. An appendix, in which are given various calculations and tables involved in the discussion of several points raised in the book, and a useful index, complete the volume.

A. TAYLOR.

### THE IRON MANUFACTURE IN AMERICA

*On the American Iron Trade and its Progress during Sixteen Years.* By Sir Lowthian Bell, F.R.S. (Edinburgh and London: Ballantyne, Hanson, and Co.)

IT is impossible, in the limited space at our disposal, adequately to review this remarkable book, in which no branch of a very comprehensive subject appears to have escaped the author's close attention.

So full of detail and so exhaustive of the subject-matter are the various sections into which the work is divided, that we can do little more than glance at the numerous subdivisions.

The first section, dealing with international trade, dis-

cusses at length the American policy of protection. Comparison is made of American exports as affected by British free trade. Then follows a series of short articles on various subjects—the Anglo-American, imports of tinplates from this country, imports and exports of both countries, America as consumer and as exporter, and other important matters. By way of illustration copious tables are adduced with the author's deductions therefrom, and these will well reward the closest attention.

Section 2 deals with the relative cost of the necessities of life in various mining and metallurgical localities —

"In the United States the manufacturers are enriched at the expense of the agriculturist and of other consumers. Some time before the abolition of protective duties in the United Kingdom years of scanty harvests entailed a great amount of misery among the labouring population of these islands, and at all times the landed interest by the protection granted to it by law, imposed a burthen upon industry generally. This relation between land and industry is now, as we have seen, reversed in the United States, by which, according to our views, the manufacturers are enriched at the expense of the agriculturists and of other consumers.

"Circumstances have greatly changed since the repeal of the corn laws, and the general introduction of free trade in the British Isles, for we have a people, the largest food importers in the world, obtaining their supplies 3000 miles from where they are grown, frequently at prices as favourable as those charged in the cities of America itself."

Sir Lowthian Bell appears to grasp fully a difficult situation, and gives a fair summary of the relative economic position of the two countries, and though his views will hardly be endorsed in their entirety by Americans, the present statement of them cannot fail to strengthen the movement now in progress towards a modification of the existing fiscal policy.

It is somewhat out of our province here to comment upon the protective policy so ardently advocated in America, but we are of opinion that had iron manufacturers in the States adopted, even partially, our policy of free competition, they and their *employés* would now have been in a stronger position, and would have had a better prospect of successfully competing with us. It is possible that the very natural desire to foster the home industry has carried them a little too far.

In the next section the assemblage of materials on American is compared with that on British railways in an exhaustive manner.

Section 5 treats of the iron ores of the States, and is fully illustrated with maps, topographic and geological, together with the coal fields. The quantities raised at different periods are given, and show that in ten years the production of ore has been fully doubled. This is followed by a detailed account of the mines and costs of working. Pages 96-104 contain some interesting speculative matter on the genesis of iron ores, the cost of raising ore, together with chemical analyses, is compared with that of Great Britain and other countries. The importance of having iron free from phosphorus is shown. It is noted that iron ore suitable for the Bessemer acid process has been imported. In 1880 only 27.35 per cent of native ore was deemed suitable and raised for this purpose.

Treating of raw material in the States, the writer gives a vivid picture of the boundless wealth of both ore and fuel existing within a limited area. In the great Lake district there is a wide strip of country over 1000 miles long, where ore is found, and this is insignificant when compared with the immense resources of fuel. The origin of natural gas, petroleum, and its uses receive attention—"natural gas is not a suitable form of fuel for the blast furnace."

Section 9, on the manufacture of coke, is interesting. At the outset coke is defined and compared with its analogues—anthracite or native coke. The losses necessarily entailed in the manufacture of coke are discussed, together with modes of minimizing them. It is shown that it is impossible to utilise the gases evolved in coking or heating coal in the blast furnace, and how slowly this was realized in early practice.

Here the author's ripe experience comes into play. The *rationale* of coking is tersely put, together with the methods dealing with the utilization and recovery of the ammonia, tar, &c., the products of the destructive distillation of coal, "or coking," with special appliances adapted for this purpose. The comparative merits of hard and soft coke in the blast furnace are discussed. Commercial details are appended, which speak for themselves, and which appear accurate.

From the section on the manufacture of pig iron it may be gathered that the gigantic methods of procedure, and the enormous energy displayed in the business of the American iron manufacture, leave the average cautious Englishman in the rear. There is, however, the reverse side for consideration—it is questionable whether even the magnificent results before us have not been purchased at too great a cost. Enormous quantities of iron have without doubt been turned out, such as would never have been dreamt of here, but it would seem that authorities are not yet in agreement as to the relative merit of English and American practice. So far our American cousins appear satisfied, pointing triumphantly to the saving of both time and material accruing from their present practice. At the Edgar Thompson Works (page 170) one of the furnaces ran 2462 tons of iron in one week, and showed an average make of 2813 tons per week with an expenditure of only 16.80 cwt of coke per ton of iron. One needs, however, only to take Sir L. Bell's elaborate demonstration of the laws which govern the consumption of fuel in the blast furnace, and its utilization for the reduction of the ore, to see clearly that the above production is scarcely in the domain of practical work, carried out under ordinary conditions with average ores and fuel. Also (p. 162) he remarks, if Great Britain fails to offer striking examples such as are described by Mr. Potter and Mr. Gayley, yet, all things considered, a more uniform as well as loftier pitch of excellence in British furnace work can be proved.

Our space does not admit of a complete statement of Sir L. Bell's proofs, shortly, he first tabulates the work done at Middlesbrough with that of the Pittsburgh blast furnace, and absolutely demonstrates that the large makes are not altogether due to superior practice. A perusal of the tabular statement given satisfactorily accounts for the larger consumption of fuel in the English furnace.

The poorer ore of Cleveland consumes 3.48 cwt of coke, as against only 1.42 cwt in the richer ore used at Pittsburg for the future of the slag.

The quantity of slag determines the fuel required for its consumption, and here is the chief difference in the amount of fuel required, amounting to 2.06 cwt. The Clarence furnace consumed 19.99 cwt of coke per ton of iron, the Pittsburg furnace consumed 16.80, difference 3.19, and deducting 2.06 from 19.99 cwt = 17.93, showing an excess of 1.13 against the English furnace. This is practically the only margin we have for economy in the other sources of waste tabulated in Sir L. Bell's comparison of heat distribution.

A positive saving is effected of only 1.13 cwt, and reasons are given showing that, all things considered, this may be counterbalanced by the increased expenses incurred in American practice. As instance pp 172-174 there are now four furnaces in action at the Clarence works performing duty well after 17½ years' service, as against the hard-driven furnaces in America with lining worn out, and useless in one-sixth of the period.

The limitation is well defined in the following words, pp 182-183 —

"As one who has been fifty years at blast furnaces, I am greatly impressed with the pitch of excellence to which the Americans have brought this useful invention.

"While saying so much I have not in my mind the enormous makes.

"In respect to this we must remember that neither in materials nor in labour can we look for any economy in this country.

"On the subject of large makes I must admit that I failed to shake the belief of my friend, Mr E. C. Patter, that there is a great advantage in tasking the endurance of the furnace to the extent of reducing it to a wreck about every three years.

"I cannot say I am quite a convert to his creed, but recent experience, and the unswerving conviction of my American friends, have raised in my mind the disposition to make a trial of Cleveland ironstone, on what I have thought a questionable mode of action."

The question of heat intensity, or actual temperature, which must vary with the rate at which the fuel or coke is consumed, has not been mooted, and we admit there is no positive reason why it should.

Yet it is evident that a certain fuel—coke, for instance—may be so burnt as only to give a heat intensity barely sufficing for the fusion of lead. On the other hand, it may be so manipulated, *ie* rapidly consumed by a quick draught or forced blast "as to attain a heat intensity (temperature) sufficing for the fusion of pig iron."

Working with high pressure blast and driving in a large volume of air (87.15 cwt. Clarence, as against 71.20 cwt. Pittsburg, see p. 172), the heat intensity must be greater in the latter instance, and must, "according to the law of heat exchanges," result in the more rapid economic fusion of iron in the hearth, also intensifying the usual chemical reactions. This seems worth consideration; temperature is an important factor—in saying this it must not be inferred that the estimation of the calories which a given fuel evolves, and their distribution, must be

set aside; on the contrary, they remain the fundamental basis of any study bearing on the economic uses of fuel. Finally, one gathers on the whole that American practice is not universally superior to ours, and competent authorities are as a rule inclined to a compromise. In other words we might graft or partially adapt their practice to ours, so reaping the benefits of both, for something may be urged in favour of either system.

JOHN PARRY

### A COUNTY FAUNA

*The Fauna and Flora of Gloucestershire* By Charles A. Witchell and W. Bishop Strugnell (Stroud James, 1892)

IT would really be almost difficult to discuss this book in a serious spirit were it not that the publication of so ambitious a work as the *Natural History of a County* must always be regarded as a serious undertaking. The reader who has struggled through the volume will lay it down with a sigh—not of regret at leaving it, but at the thought that time has been wasted in its compilation.

A glance at the index is almost enough to condemn the book, without making any attempt at further acquaintance. Among nearly a score of errors in spelling, *subuteo*, *oesalon*, *tinunculus*, occur as three consecutive words. Nor is this carelessness by any means confined to the index. Such blemishes disfigure the book from beginning to end; and when, among a host of errors, we find such mistakes as *haliotide* and *helliborus*, we can hardly ascribe all the blame to the printer. The compilers usually give us "Cotteswold," but in the introduction the name is spelt "Cotswold," and there are pages on which both forms occur—in one case only a line apart.

A more serious fault is the want of balance in the work. The space allotted to birds occupies eighty-two pages, while the chapter on ants takes up nearly twenty, and that on wasps and bees close upon fifty pages. We may say at once that the two latter are so good, and stand out in such marked contrast to the rest of the work that, in spite of their disproportionate length, we hardly grudge a line of the room they occupy. Perhaps, however, it is the length of these papers which makes one of the writers on mosses omit "many other interesting species," for want of space. Another contributor calls his list of fungi "short and very imperfect." If the list is as complete as it is possible to make it, no one can fairly complain of its shortness; but surely it is scarcely worth while to print an avowedly imperfect list in what professes to be a County Flora.

The fauna opens with a brief account of the bats, a mere list of names, among which we look in vain for any evidence of observation. The notices of the quadrupeds contain some interesting particulars, but they present little that is new. In the article on the badger a good deal of information is given on the authority of a gentleman who appears to think no observations but his own are worthy of credence. One of his own observations is thus worded: "Any one who has caught badgers at night knows only too well that it is certain death to a dog

which is good enough to hold it in the open to follow it into an open drain large enough for the dog to reach it." Other people who have hunted badgers have found that an extremely small terrier is quite able to turn a badger from its earth, and that although the dog may be hurt, even seriously, by its formidable antagonist, the contest does not by any means mean "certain death" to it.

The chapter on birds bears evidence of having been put together in the most casual manner. Various contributors have sent in notes as to whether, in their experience, birds were rare or not, and these appear to have been printed without any attempt at summarizing. The result is that the whinchat is described in one line as "common," and in the next as "occasionally seen." The marsh tit is "rare," and also "generally distributed." The curl bunting is in one line called "rare" and "by no means rare." The coot is "rare" (!) and "frequently met with." The woodcock, according to one observer, "has been seen." If it were clear that such remarks applied to different parts of the county, there might be some sense in printing them. As they stand, they are useless and bewildering. One contributor is surprised at the occurrence of the gannet just outside the limits of the county, because "they generally inhabit the Bass Rock"! They certainly do, and "there's mile-stones on the Dover road." But perhaps there is nothing in the whole chapter which quite comes up to what we read about two starlings that one of the contributors watched "fighting furiously each bird trying to force its bill into that of the other. *He was informed that the purpose of each bird was by this means to render the opponent insensible, so as to be more easily destroyed*."

In the article on reptiles occur these remarkable words—"The slowworm is habitually 'slow,' but we know of no reptile or quadruped which, in proportion to its size, can move more rapidly."

There are several errors in spelling in the list of land and fresh-water shells, and it is rather misleading to give "Downs, under stones," for the habitat of the species here called *Bacutus*, without adding "near the sea."

*Helianthemum polysolum* is given as a Gloucestershire plant. It would be interesting to know if this is correct. The localities usually given are in Somerset and Devon.

Among the illustrations are some interesting figures of famous trees; but it seems hardly worth while to have inserted such a very ordinary-looking plate as that of the common crayfish.

Allusion has already been made to two chapters the excellence of which is all the more marked by contrast with the grandiloquent flights and the trivial details of much of this unfortunate volume. Rev W F White's paper on ants contains, as might be expected, accounts of many interesting and original observations. Mr Vincent Perkins's excellent chapter on wasps and bees, again, is extremely good, though the writer deals only with the neighbourhood of Wotton-under-Edge. That so imperfect, and, as far as much of its contents goes, we are afraid we must say untrustworthy, a book should ever have been published is matter for regret. The real "Fauna and Flora of the County of Gloucester" yet remains to be written.

## OUR BOOK SHELF

*The Chemistry of Life and Health* "University Extension Manuals." By C W Kimmins, M A, D Sc., Staff Lecturer in Chemistry, Cambridge University Extension Scheme (London: Methuen and Co, 1892.)

THIS little book is well adapted to secure the aim of the author, which is "to give sufficient information on the particular portions of the sciences involved to enable readers to appreciate fully the fundamental principles of hygiene." There can be no doubt of the importance, one might truly say, the national importance, of the spread of sound knowledge regarding the laws of health. Such sound knowledge cannot be attained except it be built upon a well-laid foundation of chemistry and physiology. To lay the foundation, and rear the structure, in a little book of 160 pages is almost impossible. Dr Kimmins has, wisely, omitted much, but what he retains is of fundamental importance, his facts are clearly enunciated and systematically arranged. A careful study of this book, especially when it is supplemented, as it is meant to be, by a course of lectures, cannot fail to be most useful. The book is written for ordinary people, not for professional students, the teaching is sound and clear. The first chapter, on the principles of chemistry, is the least satisfactory in the book, but in this chapter the author has attempted, what is surely unattainable, to give an elementary knowledge of the features of chemical action, the use of chemical symbols, and the molecular and atomic theory, in sixteen small pages. As an introduction to the study of the application of chemical facts and principles to the conditions of healthy life, the book is to be thoroughly recommended.

*Naked-Eye Botany, with Illustrations and Floral Problems* By F E Kitchener, M A. Pp 182 and fifty-two woodcuts in the text. (London: Percival and Co, 1892.)

ON turning over the pages of this book one wonders why "Naked-Eye Botany" was chosen for the title, because, although a small book, it has some reference at least to a great many things that cannot be seen with the naked eye. It is something in the way of Prof D Oliver's "Lessons in Elementary Botany," but one misses the Professor in it. On p 7 we are introduced to stomata, and physiological processes are described in some detail. Nevertheless it contains much useful matter, and with a little revision and better selections would make a very good first book. For example, the chickweed is chosen for the first lesson. But the flowers of this plant are so small and the number of parts in the various floral whorls is so variable that it is not a good subject to begin with. The "problems," or questions, also at the end of each chapter are too wide-reaching. Referring to *Aspidium Filix-mas*, we are told that the "production of the fertilized seed, more correctly called oosphere, from the prothallus, can scarcely be made out with the naked eye." Saying nothing about the name given to the fertilized body, we must protest that "scarcely" is not the word to qualify the observation.

Perhaps it is too much to ask that the headmaster of a "high school" should be acquainted with even remotely recent discoveries in physiological botany, but it would not be unreasonable to ask him to use the text-books of specialists. It is now some years since the reproduction of *Lycepodium* was fully described, yet Mr. Kitchener still teaches that the spores are of two sorts.

*The Great World's Farm, some account of Nature's Crops and how they are Grown* By Selina Gaye (London: Seeley, 1893.)

THIS is a delightful book, pleasantly written, full of information, and on the whole remarkably free from those errors, generally the results of misunderstanding, which

are the sins that do so easily beset writers on popular science. The volume, which contains some excellent illustrations, deals with "pioneer labourers," "soil-makers," "soil-carriers," "soil-binders," "field-labourers," "guests welcome and unwelcome," "nature's militia," and so forth. We do not propose to tell who or what the labourers, the guests, or the militia are. We advise those of our readers who are interested in the transactions of the Great World's Farm to get the volume and ascertain for themselves.

### LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### Measurement of Distances of Binary Stars

SOME years ago I communicated to a few astronomers a plan for measuring the distance which separates us from some of the binary stars, believing, as I did, that by using the diameters of their paths as a basis, determinations of distance could be made which are impossible with the means at present in use.

This basis could, I hoped, be calculated by first ascertaining the velocities with which the stars are moving in their paths, in a somewhat similar manner to that employed for measuring the motions of stars with the spectroscopic, except that instead of making a comparison with a hydrogen flame, the spectra of the two stars should be compared by photographing them together. The width of any double lines, which may show themselves (the one line belonging to the spectrum of the receding star, and the other to the advancing one) would be a measure of their velocities expressed in miles. Applying this information to the known period of revolution of the system, its diameter can also be expressed in miles, and this would enable one to estimate the distance from the earth if the angle between the two stars were known. This suggestion has already borne fruit, the relative velocity of some rapid, but as yet inseparable, binaries having recently been determined.

The answers received to my suggestions were discouraging, but since then instruments have been improved, and I trust that you will think the matter of sufficient importance to be brought before the notice of your numerous astronomical readers. Should any of them be able to make the necessary determination, a foundation-stone will have been laid, not only for obtaining a true idea of perhaps undreamt of stellar distances, but also of the masses of binary stars, and possibly a connection may ultimately be traced between them and the adjoining ones.

The two most brilliant binary stars are  $\alpha$  Centauri and  $\alpha$  Geminorum, and as in both these cases the paths are elongated ellipses, and the stars near their extremities, efforts should be directed towards determining their distances as suggested above.

Strawberry Hill, November 16

#### Remarkable Weapons of Defence

THE following extract from a letter from such a careful observer as Mr. E. E. Green is of such general and special interest as to require publication.

Mr. R. J. Pocock informs me that the Acaroid is almost certainly *Holothyrus coccinella*, Gerv., a species that appears to be common in Mauritius, and that in the lateral membranous area between the carapace and the cephalothoracic limbs is a distinct orifice which was regarded by Dr. Thorell as of respiratory import, but in connection with Mr. Green's interesting discovery of the existence of offensive glands in this animal it is necessary to bear in mind the possibility of its being the outlet of the organs.

The mite has such a hard integument, that being taken into the mouths of the lizards and birds that would probably prey upon it in the situations it frequents, would probably do it little or no damage if it were speedily rejected.

G. F. HAMPSON.

THE accompanying insects—apparently Orobatiid mites—were found by me in the district of Tallawakelle, Ceylon (alt.

4600 ft.), under stones and rocks in damp, shady situations. It was only by accident that I became aware of their remarkable weapons of defence—an exceedingly pungent secretion.

About five hours after handling one of these insects I accidentally touched my tongue with my finger. Immediately an extraordinarily pungent, galvanic sensation or taste commenced rapidly to spread over my mouth, quickly reaching my throat. Rinsing my mouth and gargling with hot water failed to arrest the progress of the sensation, which was accompanied with excessive salivation. The unpleasantness lasted for several hours, and then died away without any further consequences. I also unconsciously rubbed my face, at the angle of the eye, with the same finger, after which a rather pleasant warmth spread over that part of my face, and was distinctly perceptible the following morning.

I could not for some time trace the cause of this effect. I at first put it down to the agency of a fungus that I had been carrying, but a further experiment negated this idea. I afterwards tested the insect, and found it to be the real agent. The experiment was repeated at my suggestion, by a medical friend—Dr. R. J. Drummond—who can testify to the result. He described the sensation as somewhat like that produced by the strongest menthol. We both noticed that it had a numbing effect upon the mucous membrane of the mouth.

It is evident that this property must be a very efficient protection to the insect. The rapidity with which the secretion acts would cause it to be very quickly ejected if picked up by either a bird or a lizard—the only enemies that would be likely to attack it.

E. ERNEST GREEN.

Eton, Pundulorja, November

#### A Suggestion

AS very shortly now NATURE will reach its jubilee volume, I hope you will permit me, as an uninterrupted subscriber for nearly twenty years, to offer a suggestion with regard to that occasion.

As the volumes of NATURE contain original contributions, observations, and notes in all branches of science, more varied and valuable than are to be found in any other scientific periodical publication in existence, there is not a worker in whatever branch he may be engaged, that does not find it necessary to be continually referring to its pages, but, unfortunately, through lack of a general handy index, he discovers what he wants only after the expenditure of a very great deal of time and worry.

I write, therefore, not only in my own name, but (by request in a private way) in that of a large number of fellow-workers in the subjects in which I am myself specially interested—biology, palaeontology, anthropology, geography—to suggest that you should celebrate the jubilee of NATURE by conferring on your readers the immense boon of a classified index to its contents.

During some investigations I was making in 1876-7 I so felt the need of a collected index that I went to the trouble of compiling for myself one, up to that date, classified according to sciences, subdivided again according to the sections of each, which in subsequent work saved me weeks of time and trouble. To my regret, this MS got lost or destroyed, and there is nothing in connection with NATURE that I, and I am certain every other worker, would now hail with greater satisfaction than the announcement that the means of reaching with expedition and precision the treasures at present so deeply buried in your (nearly) fifty priceless volumes, will be secured within our reach with its jubilee volume.

OLD SUBSCRIBER.

#### Superstitions of the Shuswaps of British Columbia.

REFERRING to the above, as recorded by Dr. George Dawson, F.R.S., in the Transactions of the Royal Society of Canada, and included in your Notes of last issue, in which attention is called to the belief among the Shuswaps and some other North American races, that small lizards enter the bodies of men, pursuing them, and devouring their hearts, I was at once struck with the almost exact resemblance of this belief to one very generally prevailing in Ireland, as regards common water Newts, which go by the name of Man eaters (pronounced Man-aters). This I can testify to from personal knowledge, but it has been accidentally confirmed by an experiment which I hope I may be pardoned for referring to. Where I reside are three Irish servants, to whom I caused to be shown a drawing of the Water Newt, and with the request that I might be told its

name, and anything they knew about it. One of these, a Galway woman, speaking Irish better than English, gave me the name in her language (which I won't attempt to transcribe, for it was a very long one), and also said that the animals were well known to jump down people's throats to their certain destruction.

Athenæum, December 24.

### The Great Ice Age

THERE is in the Astronomical theory of the Ice Age a point of some importance, not mentioned by Sir Robert Ball in his interesting work on this subject, to which I invite the reader's attention. I mean the *slowness with which the difference between the length of summer and that of winter is varying in the neighbourhood of its maximum*.

To compute this difference and its mean value, we put

$a$  = the mean distance of the earth from the sun,

$e$  = the eccentricity of the earth's orbit,

$\omega$  = the longitude of the perihelion of the earth's orbit,

$T$  = the length of the year in mean solar days,

$\Delta$  = the difference between the lengths of the two seasons in mean solar days,

$\eta$  = the mean value of this difference during the interval between the two dates, corresponding to  $\omega - \omega_1$  and  $\omega = \omega_2$ , >  $\omega_1$ .

Then, the eccentricity remaining always extremely small, the difference between the areas of the two segments in which the line of the equinoxes divides the earth's orbit, may be put—and with sufficient accuracy,

$$= 2ae \cdot 2a \sin \omega = 4a^2 e \sin \omega$$

Hence, we find, by Kepler's first law,

$$\Delta = \frac{4a^2 e \sin \omega}{\pi a^2 \sqrt{1 - e^2}}$$

and consequently, by neglecting the third and higher powers of  $e$ ,

$$\Delta = \frac{4Te \sin \omega}{\pi}$$

Observing that the eccentricity remains sensibly constant for a period of time, which is doubtless to be reckoned by many tens of thousands of years, we obtain, by means of the formula just found,

$$\eta = \frac{4Te}{\pi} \int_{\omega_1}^{\omega_2} \sin \omega d\omega = \frac{4Te}{\pi} \frac{\cos \omega_1 - \cos \omega_2}{\omega_2 - \omega_1}$$

Finally, by substituting the numerical values of our constants, we shall have the following formulæ for computing  $\Delta$  and  $\eta$ —

$$\Delta = 465e \sin \omega,$$

$$\eta = \frac{465e (\cos \omega_1 - \cos \omega_2)}{\omega_2 - \omega_1},$$

positive values designating that in the Northern Hemisphere and negative values that in the Southern Hemisphere the summer exceeds the winter.

From the first formula we deduce that, for a given eccentricity, the disparity in the lengths of the seasons shall be as great as possible when the line of the equinoxes is perpendicular to the axis major of the orbit. Now, putting  $e = 0.071$ , the maximum eccentricity, the values of  $\Delta$  and  $\eta$  for a few values of  $\omega$  are as follows—

$\omega$	$\Delta$	$\omega_2 - \omega_1$	$\eta$
90	33	10	
85 or 95	33	95 - 85	33
80 or 100	32½	100 - 80	33
75 or 105	32	105 - 75	32½
70 or 110	31	110 - 70	32
65 or 115	30	115 - 65	32
60 or 120	28	120 - 60	31½
55 or 125	27	125 - 55	31
50 or 130	25	130 - 50	30
45 or 135	23	135 - 45	29½

If we remember that the longitude of the perihelion increases in about twenty-one thousand years from  $0^\circ$  to  $360^\circ$ , then, it will be seen by inspecting these results that, for example, during the interval between the two dates corresponding to  $\omega = 65^\circ$  and

$\omega = 115^\circ$ , &c. during a period of nearly three thousand years, the mean difference between summer and winter will be thirty-two days, and that during this period the difference itself will never sink below thirty days.

Deventer, Netherlands, December 17

### Aggressive Mimicry

IN his last letter Mr. Poulton observes that I am one of "four recent writers" who have made use of the collections in the Natural History Museum and the Museum of the Royal College of Surgeons, for the purpose of illustrating the phenomena of mimicry between *Volucella* and *Bombex*. This is the case, but I should like to add that the species which I have depicted are not *V. bombylans* and *B. muscorum* (the questionable resemblance of which in nature, and the erroneous labelling of which in the "show cases," constitute the grounds of Mr. Bateson's somewhat "aggressive" criticism on other "recent writers"), but *V. bombylans* and *B. lapidarius*, where the fact of resemblance can admit of no doubt ("Darwin and After Darwin," p. 329). Indeed, Mr. Bateson fully recognizes the close similarity in appearance between these two species, and, as I refrained from giving the hypothetical explanation of it to which he objects, I avoided all the issues which have since been raised in the NATURE correspondence.

Madeira, December 15

GEORGE J. ROMANES

### Artificially Incubated Eggs

I HAVE been repeatedly informed by poultry-growers and market men that hens raised from artificially incubated eggs were much less fertile than those produced in the natural way. My information has been derived from persons who did not even know each other. It occurs to me that if true it is a curious matter and worthy of some attention.

Brown University Herbarium, Providence, R. I.

December 10

### THE PROPOSED UNIVERSITY FOR LONDON

A GENERAL meeting of the Association for Promoting a Professorial University for London was held on Wednesday, December 21, when a report, which we print below, was presented by the Executive Committee. We would call the attention of our readers to the penultimate paragraph of this report, which indicates the existence of an agreement, on matters of principle between the Senate of the University of London and the Association.

The last general meeting of members of the Association was held on June 14, 1892, when the Executive Committee presented for approval a series of proposals for the organization of a University in London. These proposals were adopted as the formal expression of the objects of the Association.

Since that meeting the efforts of the Committee have been directed to the furtherance of the principles embodied in the above-mentioned proposals—by endeavouring to obtain the adhesion of literary and scientific men, and of other persons interested in the matter, by organizing a body of evidence to be presented to the Gresham University Commission, and by such other means as have suggested themselves from time to time.

Immediately after the last general meeting, Prof. Huxley became a member of the Association, and consented to accept the office of president. Sir Henry Roscoe and the Master of University College, Oxford, consented to become vice presidents; and the first of these gentlemen has since been an active member of the Executive Committee.

The number of members of the Association is now one hundred and fifty.

Evidence in support of the principles of the Association has been given before the Gresham University Commission by the following gentlemen.—Prof. Ayrton, Mr. F. V. Dickins, Prof. G. C. Foster, Principal Heath, Prof.

Henrici, Prof Huxley, Prof Ray Lankester, Prof Henry Nettleship, Prof Pearson, Sir H Roscoe, Prof. Rucker, Dr Russell, Prof T E. Thorpe, Prof Unwin, Dr Waller, Dr Windle, Prof Weldon.

During the month of November the Committee were informed that a Committee of the Senate of London University had drawn up a series of resolutions, to be submitted to the Royal Commission. Your Committee therefore requested the Vice-Chancellor to allow its members to address the Committee of the University Senate in support of the proposals of the Association. The Vice-Chancellor replied by inviting the Executive Committee of the Association to attend a meeting of the University Committee on Wednesday, December 7. At this meeting the objects of the Association were explained by the President, Sir Henry Roscoe, and Prof Weldon, and the Vice-Chancellor in reply made an important statement, to the effect that the resolutions which were put forward by the Committee of the Senate were intended to be understood in such a manner as to render them perfectly consistent with the programme of the Association. The resolutions proposed by the University Committee, and since adopted by the whole Senate, are as follows —

The Senate having reason to believe that a distinct expression of opinion may be useful to the Commissioners at the present stage of the inquiry, desire to recall to their attention the fact that during last year the Senate approved a Scheme for a Reconstitution of the University which provided for the constitution of Faculties consisting of teachers and of Boards of Studies in each Faculty, and for the election of members of the Senate by the Faculties, and that the Scheme further proposed to confer on the University power to hold real property and to accept grants, gifts, devises, and legacies for the purposes of the University, including the establishment of Professorships and Scholarships, whether attached or not to any particular College, and the furtherance of regular liberal education and of original research.

The Senate now desire to state that, if in accordance with the decision of the Commissioners, the Senate is prepared, in order to promote the efficiency of the University, and with a view to its reorganization as a Teaching University in and for London, without curtailment of the functions which it now discharges—

(a) To establish and incorporate with the University Faculties in Arts, Science, Laws, and Medicine, and Boards of Studies acting thereunder

(b) To provide for the incorporation with the University of Teaching Institutions of the higher rank

(c) To utilize, with their consent, existing organizations for higher culture, and subject to such utilization to institute and maintain Professorships and Lectureships, whether for academical or other purposes, and generally to assume such functions as may be required for the furtherance and superintendence of a regular liberal education, and for the promotion of original research

(d) To accept and administer fees and such other funds, public or private, as may be necessary, and may be granted or given for the purposes of the reorganized University

(e) To provide for the adequate representation of the Professoriate on the Senate.

The Committee regret that Prof. Pearson, whose energy and enthusiasm have been of such essential service to the Association, has felt obliged to retire from the office of Secretary. His place has been taken by Prof. Weldon.

#### THE MANCHESTER MUNICIPAL TECHNICAL SCHOOL.

IN his interesting address on technical education, when distributing the prizes of the Manchester Municipal Technical School, on the 19th inst., Mr. Balfour pointed

out that the occasion was an important one, not only in the history of technical instruction in Manchester, in the history of the Corporation of that city, but also in the commercial and manufacturing history of Manchester itself, since this was the first public occasion of the distribution of prizes to the scholars of the Technical School and the School of Art since these schools were taken over by the municipality, and supported out of the public funds of the city. The fact that the Corporation of the northern metropolis has taken possession of the School of Art and of the flourishing Technical School, founded a few years ago on the site of the old Mechanics' Institution, is one which may well claim the attention of the leading statesmen of our time, and Mr. Balfour has done good service to this great educational movement by thus placing prominently before the country the part which our municipal authorities are now playing in the matter. Fully alive to the revolution which these changes are bringing about in our educational system, Mr. Balfour, speaking to the teachers and students, insisted that there is now thrown upon them something more than personal responsibility, something more than the desire for self-advancement. They are concerned, he said, in a national work, and ought to look at it from a national point of view, and it is this public aspect of the question which justifies and more than justifies the Corporation for having taken up this great work and for having created the greatest technical school at present existing in England, but which, great as it is, is still in its infancy, and will yet show developments which will astonish those who are now devoting their time to it in so public-spirited a fashion.

Then spoke Mr. Councillor Hoy, the chairman of the Technical Education Committee of the Corporation, and in thanking Mr. Balfour for his "thoughtful and charming address" added that it was only nine months since these schools were handed over to the Corporation, that they had to master the whole machinery of the education, to arrange all the details of the transfer, but that in addition they had plunged right away into the necessary steps for erecting a new and enlarged school.

So it is evident that the men of Manchester do not allow the grass to grow under their feet. They know that the business they have undertaken is a big one, and they, like good business men, are prepared boldly to meet the necessities of their position. How boldly and how completely they propose to do so will be seen when we learn what are the proposals which they have made for carrying on their work, for making the necessary preparations, for giving the highest and most complete technical training which can be given in all those matters upon the satisfactory accomplishment of which, the industry and commerce of the vast district of which Manchester is the centre depends. At present the work of the Technical School is carried on in three different buildings, one the old Mechanics Institution where the great bulk of the teaching is done, another in an old warehouse fitted to suit the wants, as far as may be, of the electrical engineering department, and a third in the buildings of a school where a very completely-equipped department for the scientific study of the cotton manufacture is arranged. Needless to say that none of these three buildings provide sufficient or adequate accommodation for the proper practical teaching and illustration of their subjects, and no sooner had the Corporation Committee become acquainted with what they had to do, and the means placed at their disposal for doing it, than they made up their minds that a new building must be erected fully representative of the present needs, and with room, if possible, for future developments.

But before committing themselves to plans or estimates, this committee wisely determined to see with their own

ST. LOUIS TECHNICAL SCHOOL CONVENTION

DESIGNED BY

JOHN C. SMITH & SONS, ARCHITECTS

eyes what was doing and had been done elsewhere. They visited the English schools, such as they are, and, more important, they went abroad and inspected the well-known technical schools on the continent, and on their return they issued an interesting report containing not only an account of what they saw and learnt, but the conclusions they drew as to how far their Manchester school should be modelled on foreign lines. This journey of inspection gave the members of the committee a new and enlarged view of their duties, and they returned home with the determination that if they could not approach the size of such buildings as the Zurich Polytechnicum or the Technical High School of Charlottenburg, at any rate they would put up a school which should be as complete in its parts as any similar institution abroad and capable of doing for their centre work equally useful and of exerting an equally beneficial influence on their population as any of the foreign schools. Some captious critics were loud in their condemnation of such a way of spending public money as that of sending a number of Manchester men on an educational tour abroad. In fact, no money could be or has been more judiciously or more economically spent. Without a knowledge from personal observation of what is doing elsewhere, these gentlemen could not possibly have carried out their business to a successful issue, with such a knowledge they can and will do it.

Fortunately for Manchester, the necessity for technical training of the people was long ago preached by one of her most distinguished sons, the late Sir Joseph Whitworth, and his legatees, knowing his views, presented a site for the school of 5000 square yards, situated in the centre of the city, and well placed as regards light and air. On this site the Corporation have decided to build a spacious, not to say magnificent, school, a perspective view of which is found on the opposite page. The whole of the site, including 770 yards in addition given by the Corporation, is to be covered by buildings, and in it ample accommodation will be found for the work carried on in the present temporary premises. This will include engineering, mechanical, electrical, civil and sanitary, the chemical industries, the cotton manufacture, spinning and weaving, the building trades, dyeing and calico printing, metallurgy, letterpress and lithographic printing, and other minor industries, industrial art and design, and the subjects classed under the heads of commercial and economical instruction. And in addition to these proper accommodation for the teaching of the pure sciences, mathematics, foreign languages, to say nothing of manual instruction and gymnastics. All these matters require means of giving practical instruction, not only lecture rooms, but laboratories, workshops, and museums, so the problem of satisfying all their needs is a complicated one, but one which the committee are determined to do their best to carry out. The size of the proposed building called forth a large number of competing designs from some of the first architects of the day, and the first premium was awarded by the Committee, assisted by Mr Waterhouse, R.A., to Messrs Spalding and Cross, of London. Their design is in Renaissance style of the early French period, and the internal arrangements are made with the view of giving as much light as possible. The material is red brick with terra cotta facings, it is roofed with green Whitland Abbey slates. The building will be fireproof throughout, and the flooring covered with wood blocks, except in the case of the dyehouse and laboratories, where impervious paving is needed. One great desideratum in such a building is proper ventilation; this will be arranged on the plenum or plus pressure system, the air being pumped throughout the building by fans worked by electricity, and the lighting will also be electrical. The building is six stories high, none of the rooms will be lower than 15 feet clear, and averaging from 25 to 30 feet in depth. The class rooms, lecture theatres, drawing and designing offices, laboratories, library, work-

shops and administrative department, as well as the students' and lecturers' rooms, are all lighted from the face of the building with wide continuous corridors all round each floor, lit from internal areas, and each department will be as far as possible separate and self-contained. The total available floor-space exceeds 150,000 square feet exclusive of the corridors. The main entrance hall is 85 by 50 feet, and it is to be utilized as an industrial museum, on the first floor is a public lecture hall 30 feet high, and of the above dimensions. On the third floor is the chemical laboratory arranged for 80 working benches. Two independent staircases, as well as a spacious passenger lift give access to the different floors, and extra exits are provided in case of fire. The basement, which is only seven feet below the ground line, is to be fitted with heavy machinery and other apparatus used in industrial operations on a considerable scale. Here we find the electrical and mechanical workshops and testing machinery, rooms for purposes in which stability is necessary, experimental steam engine, dynamo, and secondary battery rooms, spinning and weaving machinery for cotton and silk, rooms for bleaching, dyeing, and finishing; plumbers', bricksetters', and masons' workshops, shops for repairs, and construction of new apparatus, &c. The upper stories contain the laboratories, general and special, lecture rooms, drawing offices, gymnasium, library, and students' reading and common rooms.

The following is the space allotted on the various floors for the several departments —

	Sq. feet.
1 Administration, Museum, Lecture Hall, Library, Reading Room, Gymnasium, and other offices	26,837
2 Mechanical Engineering	18,266
3 Applied Physics and Electrical Engineering	13,666
4 Textile Trades	19,211
5 Applied Chemistry, Dyeing, &c., Metallurgy	29,132
6 Building Trades	10,922
7 Letterpress and Lithographic Printing	2,798
8 Industrial Design	13,453
9 Commercial Subjects	11,844
10. Domestic Economy Subjects	6,461
Total	152,690

As if to indicate the determination to make the utmost of their building, the Committee have asked Sir Howard Grubb to design a small astronomical and meteorological observatory on the roof! This in the centre of smoky Manchester, but experts say that even here much useful work can be done.

The estimated cost of the building, including fittings, apparatus, and machinery is about £125,000; towards this sum the Committee have available £14,000 balance of profit from the Jubilee Exhibition; £5000 promised by the Whitworth trustees; and the property belonging to the old schools estimated at £31,000. The remainder of the sum, about £75,000, the Corporation will borrow for a period of thirty years on the security of the 1d rate. This great school will be governed by a Committee of thirty-six persons, twenty-four of whom are members of the City Council, twelve being chosen from the public interested in the progress of Industrial and Commercial Education.

Enough has been said to give the reader an idea of the scale and completeness of the proposed Municipal School. To work this properly will cost nearly £10,000 per annum. The fees will be low, but nevertheless will bring in a goodly sum, and the funds available from the Local Taxation (Customs and Excise) Act of 1890—commonly termed the beer money—will provide the remainder. Such a school, holding as it will do an intermediate position, between the Board Schools on the one hand, and highest University Education as given in the Owens

College on the other, cannot fail to exert a most important influence on the future development of trade and manufactures in Lancashire. What Manchester is doing in this magnificent way, other towns, notably Birmingham, Salford, Stockport, Oldham, Bolton, and others, are also doing, it is true on a smaller scale, but still in a manner sufficient for their needs. How long will it be before London moves? H. E. ROSCOE

### THE MONT BLANC OBSERVATORY<sup>1</sup>

THE project of establishing a meteorological and astronomical observatory on the summit of Mont Blanc has, under the care of M. J. Janssen, of the Meudon Observatory, made considerable progress during this year's summer months. It has been decided to use the snow itself as a foundation on which to rest the building. That this can be done with security was shown by some experiments carried out at Meudon last winter. A miniature mountain was made of snow pressed to the same density as that which is found on Mont Blanc at a depth of one or two metres below the surface. This being

made level at the top, discs of lead 35 cm. in diameter, and weighing each about 30 kgr., were placed on the snow, one upon the other. After twelve of these had been piled up, with an aggregate weight of 360 kgr., they were removed and the depth of the impression measured. It was not more than 7 or 8 mm. Thus a structure measuring 10 m. by 5 m. might safely weigh 187,000 kgr. without sinking into the snow more than a few centimetres.

The summit of Mont Blanc is formed by a very narrow edge of rock 100 m. long, running from west to east, and covered by snow which is thicker on the French than on the Italian side. The level of this snow has not shown

any important oscillations throughout a number of years. To obviate the disturbing effects of the storms which frequently rage round the summit, the building is constructed in the shape of a truncated pyramid, the lower floor being sunk into the snow. The rectangular base measures 10 m. by 5 m. The upper floor, which will be devoted to the observations, is covered with a flat roof, towards which ascent is made by a spiral staircase leading from the basement upwards through the whole building, and above the flat roof to a small platform destined for meteorological observations.

The whole observatory has double walls to protect the observers against the cold. The windows and doors are also double, and provided on the outside with shutters closing hermetically. The floor is made of double planks, and furnished with trap-doors giving access to the snow supporting the observatory, and to the screw-jacks placed in position for adjusting the level of the building in case the snow should yield. The building will be provided with heating apparatus and all the furniture necessary to make habitation at such an altitude possible.

Up to the present the observatory has been transported in parts to Chamounix. On the Grands-Mulets a cottage has been erected for the use of the workmen and for storing the things destined for the observatory.

On the Grand Rocher Rouge another cottage has been built, only 300 m. below the summit, in which the workers and observers can, if necessary, take refuge. Three-quarters of the materials for the observatory have been transported to the Grands-Mulets (3000 m.) and the rest to the Rocher Rouge (4500 m.).

Next year the erection on the summit will be carried out. An astronomical dome, which is to complete the observatory, will also be taken in hand. The work done up to now has been carried out under great difficulties, owing to the fact that everything had to be carried by hand. But no accident has, so far, marred the success.

Dr Capus, who accompanied M. Bonvalot in his well-known expedition to the Pamir, has promised his assistance for certain observations. But the observatory will be international, and open to all observers who wish to work there. E. E. F. d'A.

### M. PASTEUR'S SEVENTIETH BIRTHDAY

FRENCHMEN may be cordially congratulated on the enthusiasm with which the seventieth birthday of M. Pasteur was celebrated on Tuesday. It afforded a most striking illustration of the way in which they appreciate the services rendered by men of science. But the celebration was not, of course, one in which only the countrymen of M. Pasteur were interested, representatives of science from many different parts of the world were present to do honour to the illustrious investigator.

The ceremony took place in the great amphitheatre of the Sorbonne, which was crowded by a brilliant assembly including many of the foremost men of the day, not merely in science but in politics and literature. M. Carnot was present, and among those who supported him was M. Dupuy, the Minister of Public Instruction. M. Pasteur entered the amphitheatre leaning upon the arm of his son and upon that of the President of the Republic. All who were present rose to their feet and greeted the hero of the day with loud cheers. M. Pasteur, who was much affected by this reception, took his place beside his colleagues of the Institute and a row of Ambassadors and Ministers.

The proceedings were opened by M. Bertrand, perpetual secretary of the Academy of Science, who acted as chairman. At his request an address was delivered by the Minister of Public Instruction, who spoke eloquently of the great qualities displayed by M. Pasteur during his splendid career, and of the benefits conferred on man-

<sup>1</sup> Janssen, *Comptes rendus*, November 28.

kind by his labours. After the Minister came M d'Abbadie, the President of the Academy, who, expressing the congratulations of the Institute, presented to M Pasteur the large gold medal which had been struck in commemoration of the day. The medal bears on the obverse a likeness of M Pasteur, while on the reverse is the following inscription: "To Pasteur, on his seventieth birthday, from grateful science and humanity, Dec 27, 1892." M Bertrand also spoke, and both his speech and that of M d'Abbadie were cordially applauded. Sir Joseph Lister, one of the delegates sent by the Royal Society, was warmly greeted. He read in French the following address:—

"M Pasteur, the great honour has been accorded me of offering you the homage of medicine and surgery. There is certainly not in the entire world a single person to whom medical science is more indebted than to you. Your researches on fermentation have thrown a flood of light which has illuminated the gloomy shadows of surgery, and changed the treatment of wounds from a matter of doubtful and too often disastrous empiricism into a scientific art, certain and beneficent. Owing to you, surgery has undergone a complete revolution. It has been stripped of its terrors, and its efficiency has been almost unlimitedly enlarged. But medicine owes as much to your profound and philosophic studies as does surgery. You have raised the veil which had for centuries covered infectious diseases. You have discovered and proved their microbic nature, and, thanks to your initiative, and in many cases to your own special labour, there are already a host of these destructive disorders of which we now completely know the causes. 'Felix qui potuit rerum cognoscere causas.' This knowledge has already perfected in a surprising way the diagnosis of certain plagues of the human race, and has marked out the course which must be followed in their prophylactic and curative treatment. In this way your fine discoveries of the attenuation and reinforcement of virus and of preventive inoculations serve, and will serve as a lode-star. As a brilliant illustration, I may note your studies of rabies. Their originality was so striking that, with the exception of certain ignorant people, everybody now recognizes the greatness of that which you have accomplished against this terrible malady. You have furnished a diagnosis which immediately dispels the anguish of uncertainty which formerly haunted him who had been bitten by a dog mistakenly supposed to be suffering from rabies. If this were your only claim on humanity, you would deserve its eternal gratitude. But, by your marvellous system of inoculation against rabies, you have discovered how to follow the poison after its entry into the system, and to conquer it there. M Pasteur, infectious maladies constitute, as you know, the great majority of the maladies which afflict the human race. You can therefore understand that medicine and surgery are eager on this great occasion to offer you the profound homage of their admiration and of their gratitude."

Among other addresses was a striking speech by the Mayor of Dôle, M Pasteur's birthplace. After the presentation of gifts by foreign delegates, M Pasteur rose and spoke a few words, which, according to the Paris correspondent of the *Times*, were "broken by sobs." A speech was then read for him by his son. In this speech, as reported in the *Times*, M Pasteur said, after referring to M Carnot's presence:—"In the midst of this brilliant scene my first thought turns with melancholy to the recollection of so many scientific men who have known nothing but trials. In the past they had to struggle against the prejudices which stifled their ideas. These prejudices overcome, they encountered obstacles and difficulties of all kinds. Even a few years ago, before the public authorities and the Municipal Council had provided science with splendid buildings, a man whom I

loved and admired, Claude Bernard, had for a laboratory, a few steps from here, nothing but a low damp cellar. Perhaps it was there he was struck by the malady which carried him off. When I heard of the reception intended for me, his memory rose first of all to my mind. I hail that great memory. It seems that you have desired by an ingenious and delicate idea to make my entire life pass before my eyes. One of my Jura countrymen, the Mayor of Dôle, has brought me a photograph of the humble house where my father and mother lived under such difficulties. The presence of all the pupils of the Polytechnic School reminds me of the glowing enthusiasm with which I first entered on the pursuit of science. The representatives of the Faculty of Lille recall for me my first studies on crystallography and fermentations, which opened quite a new world to me. What hopes filled me when I discovered that there were laws behind so many obscure phenomena! You have witnessed, my dear colleagues, by what a series of deductions I have been enabled as a disciple of the experimental method to arrive at physiological results. If I have sometimes disturbed our academies by somewhat livelier discussions, it is because I was passionately defending truth."

"You, lastly, delegates of foreign nations, who have come so far to give France a proof of sympathy, you afford me the most profound gratification which can be experienced by a man who invincibly believes that science and peace will triumph over ignorance and war, that peoples come to an agreement not to destroy, but to build up, and that the future will belong to those who have done most for suffering humanity. I appeal to you, my dear Lister, and to you all, illustrious representatives of science, medicine, and surgery. Young men, trust those certain and powerful methods, only the first secrets of which we yet know. And all of you, whatever your career, do not allow yourselves to be infected by vilifying and barren scepticism, do not allow yourselves to be discouraged by the gloom of certain hours which pass over a nation. Live in the serene peace of laboratories and libraries. Consider first of all, 'What have I done for my education?' and then, as you advance, 'What have I done for my country?' until the moment when you will perhaps have the immense happiness of thinking that you have contributed in some way to the progress and welfare of mankind. But whether your efforts are more or less favoured in life you must, on nearing the grand goal, be entitled to say, 'I have done what I could.' I express to you my profound emotion and warm gratitude. Just as, on the back of this medal, the great artist Roxy has concealed under roses the date of birth which weighs so heavily on my life, so you have desired, my dear colleagues, to give my old age the spectacle which could most delight it—that of these eager and loving young men."

This closed the ceremony. M Carnot, before quitting the building, walked over to M Pasteur and embraced him. The celebration was one of which France has good reason to be proud, and Englishmen may well regret that such a demonstration, common to governors and governed, would in this country be impossible.

## NOTES

THIS week the American Society of Naturalists has been holding at Princeton, N.J., its eleventh annual meeting, the chair being occupied by Prof Henry F Osborn, Columbia College, New York. On Tuesday a lecture was to be delivered by Dr. C Hart Merriam on the Disk Valley Expedition (illustrated). On Wednesday, after the transaction of general business, the following reports on marine biological laboratories were to be read:—The Sea Isle Laboratory, by Prof J A Rider, University of Pennsylvania, a marine station in Jamaica, by

Prof E A Andrews, Johns Hopkins University, the marine laboratories of Europe, by Dr D Bashford Dean, Columbia College, and the outlook for a marine observatory at Woods Holl, by Prof C O Whitman, University of Chicago. In the evening the annual dinner of the society was to be held, and the president's address was to be delivered. The following are the principal arrangements for to-day (Thursday).—A paper is to be read by Dr C W. Stiles, Agricultural Bureau, Washington, on the endowment of the American table at Naples, and reports are to be read on botanical explorations in Florida, by Prof. W P Wilson, University of Pennsylvania, the summer work of the U S Fish Commission Schooner *Grampus*, by Prof William Libbey, Junr, Princeton College, and expeditions of the American Museum of Natural History into New Mexico, Wyoming, and Dakota, by Dr J L Wortman, American Museum Natural History. Then will come the annual discussion, the subject being, What were the former areas and relations of the American Continent, as determined by faunal and floral distribution? The following papers will be read.—Introduction, and evidences from past and present distribution of mammal, by Prof W B Scott, Princeton College, evidence from past and present distribution of reptiles, by Dr George Baur, University of Chicago, evidence from the distribution of birds, by Prof J A Allen, American Museum of Natural History, and evidence from the distribution of plants, by Dr N L Britton, Columbia College. Special meetings have been held by the American Societies of Anatomists, Morphologists, and Physiologists.

We learn, from the *Oesterreichische Botanische Zeitschrift*, of the death, at Vienna, of the veteran palæontologist, Dr D Stur, Director of the Imperial Geological Institute in that city, and author of several finely illustrated works on palæo-phytology.

DR VOLKENS, Privatdocent at the University of Berlin, and Dr Lent are about to start for East Africa, where they propose to carry on scientific investigations. The former has received a grant from the Prussian Academy of Sciences, and will devote himself especially to botanical study. Dr. Lent has received aid from the German Colonial Society, and will give especial attention to geology.

DR F BUCHANAN WHITE has presented his fine collection of lepidoptera to the Museum of the Perthshire Society of Natural Science, which is in process of being greatly enlarged. The collection contains twelve thousand specimens, which have been collected by Dr White in many parts of Europe, though mainly in Great Britain and largely in Perthshire. Many are type specimens, which have been described and figured by the collector in his numerous descriptive papers, and several represent species that have now become extinct.

DURING the latter part of last week an area of low pressure lay to the south-westward of our islands, causing south-easterly gales on our western coasts. This disturbance, however, although it advanced from off the Atlantic, remained comparatively stationary for two or three days, during which time the weather continued fine and dry over England. At the close of the week the low pressure area gave place to an area of high barometer readings, which gradually spread over the United Kingdom from the continent, bringing dry weather and severe frost, with fog in many places. The thermometer in the shade fell to 9° in Leicestershire, and to 17° in London in the night of the 26th, and in many places the day temperature continued much below the freezing point during both Monday and Tuesday. At this time the anticyclone had become thoroughly established, and the area of cold was increasing both in size and intensity, although the conditions in the extreme north indicated a possible change. The *Weekly Weather Report* for the period ending

the 24th inst shows that temperature was above the mean in all districts, being as much as 5° or 6° over Ireland. During the early part of the week the night minima were very high for the time of year. Rainfall was less than the mean in all districts, the deficiency being most considerable in Scotland and in the south-west of England. Bright sunshine was also very deficient, in Scotland and Ireland there was only from 2 to 3 per cent of the possible amount.

THE Weather Bureau of the U.S. Department of Agriculture has published some valuable "Observations and Experiments on the Fluctuations in the Level and Rate of Movement of Ground-water on the Wisconsin Agricultural Experiment Station Farm, and at Whitewater, Wisconsin," by Franklin H. King. The author holds that a careful and detailed study of the movements of ground-water ought to supply very important knowledge bearing upon the contamination of drinking waters and the spreading of certain classes of contagious diseases, and thus help to place the water supply for both urban and rural purposes under better sanitary conditions. Every advance which is made towards the increase of yield per acre necessarily means an increased demand for water, so that market gardeners even in Wisconsin and Illinois, where both the annual and summer rainfall is relatively large, are turning their attention, Mr King says, to the question as to the best means for providing irrigation. A rapid and economical advance in this direction demands, he thinks, a much more thorough knowledge of the movements of underground water than we at present possess. He also urges that in the utilization of natural sub-irrigation, and in the reclaiming of swamp lands for agricultural purposes, there is imminent need for new knowledge in the same direction. Mr King does not overrate the importance of his own researches. He regards them simply as preliminary studies.

H. HARENICHT, of Gotha, has contributed a paper to *Ausland* (No. 49) on the frequency of icebergs in the Gulf Stream and variations of climate, based upon the reports of icebergs published since 1883 in the pilot charts of the North Atlantic Ocean. He gives a table showing the number of bergs reported in each year in the Gulf Stream, with a summary of the temperature conditions experienced in Europe during each of the four seasons. The number of icebergs varied considerably in different years, from ten in the year 1888 to 674 in the year 1890. The table shows some unmistakable coincidences between the frequency of the bergs and the character of subsequent weather about six months afterwards. The extremely low minimum of iceberg frequency in 1888 was followed by the warmest year of the series, all the seasons of 1889 were warm over Europe. There was another less marked minimum of icebergs in 1889, and this was followed by a relatively warm year in 1890. The remarkable maximum of bergs in 1890 was followed in 1891 by the coldest winter that had occurred for twenty years, and the cold winter was followed by an abnormally cold spring and summer. The table also shows that the coincidences are more marked with iceberg maxima than with minima. Two of the latter in two successive years were followed by only one warm summer, while in the case of the maxima the decrease of temperature occurred in the next year.

MR D T MACDOUGAL contributes to *Science*, December 2, an interesting account of some explorations recently made by a botanical expedition in Idaho. The work of the expedition was planned by Dr G Z. Vasey, chief botanist of the U.S. Department of Agriculture. The results are summarized thus:—The basins of Lakes Coeur d'Alene and Pend d'Oreille and of the Clearwater and Palouse rivers were explored, the botanically unknown area in Central Idaho now being limited on the south by the Snake River basin, on the west by the Snake River

and the basin explored. About 25,000 specimens of dried plants were collected, representing nearly 1000 species, many of them undescribed forms. Valuable facts concerning general distribution of plants were obtained, since the area explored is one where the Rocky Mountain flora meets and intermingles with the Pacific coast flora in a very interesting manner, while the opportunity afforded by numerous mountain slopes for the furthering of some problems of vertical distribution was not neglected.

AN important paper on fossil mammals of the Wahsatch and Wind River Beds, by H. F. Osborn and J. L. Wortman, has been issued as a bulletin by the American Museum of Natural History, and has also been published separately. It includes a plate and eighteen figures in the text, and is devoted principally to a description of a collection made by Dr. Wortman during the summer of 1891. The authors claim that many new facts of great interest are brought out by the material in the collection. In a preliminary note it is stated that the department of mammalian palaeontology in the American Museum of Natural History was established in May, 1891, and that the purpose of the trustees is to procure a representative collection of the American fossil mammals from the successive geological horizons of the West for purposes of exhibition, study and publication. The staff consists of Prof. H. F. Osborn, of Columbia College, Curator, and of Dr. J. L. Wortman, assistant in Palaeontology. Mr. Charles Earle and Mr. O. A. Peterson are also engaged as assistants, and Mr. Rudolph Weber as draughtsman. The collections are to be made readily accessible to students, and exhibited as rapidly as they can be put together and mounted. A list of such duplicate specimens as are available for purposes of exchange is to be prepared. A series of casts of the best preserved types is also in preparation for exchange.

LAST week we printed an account of the ceremonies connected with the Tercentenary of Galileo at Padua. In addition to what was then stated we may say that after Prof. Favaro's oration the delegates were invited to present the addresses of which they were the bearers, whereupon, the English delegation having by lot been placed first in order of precedence, at the request of his colleagues, Prof. Darwin and Stone of Cambridge and Oxford, Sir Joseph Fayer spoke first, on presenting the addresses of the Royal College of Physicians of London and the University of Edinburgh, with which he was entrusted. He spoke in Italian to the following effect:—

"Profondamente commosso all'onore accordatomi dal Reale Collegio dei Medici di Londra, ed anche dall'Università di Edinburgo, nel nominarmi il loro delegato, io mi presento davanti a questa insigne adunanza, per far onore alla memoria di uno dei più grandi uomini e dei più illustri sapienti del mondo, e per render omaggio da parte del detto Collegio, così bene come dell'illustre centro di scienza e di filosofia in Scozia, all'incelto scienziato, nonché a felicitare di cuore colla massima riverenza, questo antico seggio di scienza e di filosofia in così lieta e fausta occasione, nella quale si commemorano le scoperte gloriose del celebre e rinomato filosofo, col nome del quale è intimamente collegata la sua storia passata ed anche la sua rinomanza attuale. La scienza di tutto il mondo è senza dubbio in questo luogo ora rappresentata. Da ogni parte sono venuti messaggi di simpatia, ma da nessuno forse, con maggiore premura e zelo che dei compatrioti di Harvey e Newton. Questi, impugnando la facciola caduta dalla mano morta di Galileo, la innalzò e la sostenne per illuminare le tenebre e schiarare di vera luce i luoghi finallora oscuri anche al gran filosofo stesso, l'altro avendo terminato i suoi studi ed essendo laureato in questa universalità, divenne dipoi, come socio del Collegio di Londra, famoso per le sue scoperte sulla circolazione del sangue. I suoi studi anatomici che fece a Padova svilupparono in lui quel genio al quale il mondo intero è debitore. Signori miei, non è solo allo scopritore del termometro, e, come si può dire, all'inventore del telescopio; non è neppure all'astronomo famoso

che ha stabilito il sistema eliocentrico, ed ha quasi anticipato le scoperte di Keplero, e che ha dimostrato i satelliti di Giove, le fasi del pianeta Venere, i movimenti diurni e mensili della luna e le macchie solari, non è infine all'autore del 'Saggiatore', del 'Sidereus Nuncius', e del 'Dialogo dei due Massimi sistemi del Mondo',—ma è piuttosto al fondatore della filosofia sperimentale che noi rendiamo adesso omaggio ed onore. Egli, osando, pensare ed investigare da se stesso, rigettando gli assiomi degli antichi sistemi di filosofia, anche quello di Aristotele stesso, e rifiutando gli insegnamenti della teologia dogmatica, stabilì il sistema del libero esame, affermando che la scoperta della verità dev'essere il primo motivo, e che si deve cercarla per via di sperimenti e non sull'altrui autorità, e che la verità è unica, tanto in rispetto alle scienze divine come alle umane. Ardisco dire che nessun migliore tributo si può fare al gran maestro adesso commemorato, che questa riconoscenza festiva dopo trecento anni, dell'assiduo e instancabile lavoro che ha rovesciato non soltanto il sistema Tolomaico, ma ha dato un nuovo impulso vitale ad ogni ricerca scientifica e filosofica. Signori, con queste poche parole ho tentato d'esprimere i sentimenti dell'illustre Collegio e dell'incelto Università dei quali io sono il modesto interprete, e ho l'onore di sommettere queste indirizzi, e con esse, i voti più sinceri dei miei colleghi per la prosperità futura di questa venerabile Università, la quale, molto avanti a Galileo è stata un primo centro della vita intellettuale in Europa, e che anche adesso è famosa per la sua propria eccellenza e per i suoi rapporti col gran saggio di cui si può dire, come ha detto Dante di Aristotele: 'Tutti l'ammirano, tutti onor gli fanno'."

PROF. DARWIN of Cambridge followed Sir Joseph Fayer with an interesting and eloquent address, also in Italian. He was succeeded by other delegates. We may note that every attention was shown to the foreign delegates, and the great success of the commemoration was courteously assigned by the University authorities in large measure to the sympathy and interest evinced by other nations. It is satisfactory that no inconsiderable share of this was attributed to the English, their addresses being delivered in Italian evidently afforded much pleasure.

THE *Mediterranean Naturalist*, noting the fact that new and spacious buildings are about to take the place of the old biological station at Cetta, expresses regret that no institution of this kind has yet been established in connection with the Maltese Islands. It points out that the marine fauna and flora of Maltese waters offer themselves as a rich and practically untouched field of research, the careful working out of which would be attended with scientific and economic results of the greatest importance.

THE same journal mentions that a petition is to be presented to the Governor of Malta praying that the Maltese fisheries may be more efficiently protected. At present considerable latitude is allowed both as regards the methods practised and as regards the times at which the fishing is carried on. "This," says our contemporary, "is not as it should be. No other food supply can take the place of fish, and the fisheries of the islands under adequate protection and judicious management will always be an unfailing and increasing source of wealth."

THE Department of Public Instruction in New South Wales has published in its Technical Education Series (No. 10) the first part of what promises to be a most valuable "Bibliography of Australian Economic Botany," by J. H. Maiden, curator of the Technological Museum, Sydney. Much information on the properties and uses of Australian plants, and on the products obtained from them is embodied in books of travel, in exhibition literature, pamphlets, proceedings of learned societies, professional journals, and newspapers. It is the author's object to render this scattered information convenient for reference.

A GERMAN translation, by Count Goertz Wrisberg, of Dr. W. Freese's "Elements of Agriculture," has been published by

Paul Parey, of Berlin, under the title of "Landwirtschaft in England"

THE current number of Wundt's *Philosophische Studien* contains two experimental articles—both dealing with problems of psychological optics. The first (A. Kirschmann, "Beiträge zur Kenntniss der Farbenblindheit") gives an account of a number of interesting cases of colour blindness, together with criticisms of existing theories. A unique case is that of an inherited, unilateral (left) blindness to the qualities violet, green and yellow. In the second (E. B. Titchener, "Ueber binoculare Wirkungen monocularer Reize") an attempt is made to show that stimulation of one retina is followed by an excitation process in the other. The psychophysical results are supported by recent physiological discovery.

THE following are the arrangements at the Royal Institution for the Friday evening meetings before Easter, 1893.—Friday, January 20, Prof. Dewar, F.R.S., liquid atmospheric air, Friday, January 27, Francis Galton, F.R.S., the just-perceptible difference, Friday, February 3, Alexander Siemens theory and practice in electrical science (with experimental illustrations), Friday, February 10, Prof. Charles Stewart, some associated organisms, Friday, February 17, Prof. A. H. Church, F.R.S., turacin, a remarkable animal pigment containing copper, Friday, February 24, Edward Hopkinson, electrical railways, Friday, March 3, George Simonds, sculpture considered apart from archæology, Friday, March 10, Sir Herbert Maxwell, early myth and late romance, and Friday, March 17, William James Russell, F.R.S., ancient Egyptian pigments. On Friday, March 24, a discourse will be delivered by Lord Rayleigh. On March 31 and April 7 (the Fridays in Passion and Easter Weeks) there will be no evening meetings.

THE following are the arrangements for lectures at the Royal Victoria Hall in January.—January 3, Mr. Charles E. Reade on a trip through India, with anecdotes of the mutiny, January 10, Mr. A. Hilliard Atteridge on some old Belgian towns, January 17, Prof. Carlton Lambert on the romance of the stars, January 24, Dr. Dallinger on spiders, their work and their wisdom.

THE fermentative changes which the leaves of the tobacco plant are made to undergo before they are worked up and finally handed over to the public, are of the greatest importance in determining the quality of any particular tobacco. It was formerly supposed that the alteration in its condition thus brought about was due to purely chemical changes induced by the process of "sweating" which the leaf undergoes, but some interesting experiments made recently go to show that these important results are effected by special micro-organisms. In a paper read before the German Botanical Society, Suchsland gives an account of some investigations which he has been conducting on the bacteria found in different kinds of tobacco. He has examined fermented tobacco from all parts of the world, and found large numbers of micro-organisms, although but few varieties, mostly only two or three different species in any particular brand and but rarely micrococci forms. But what is of especial interest is the discovery that pure cultures of bacteria obtained from one kind of tobacco and inoculated on to another kind, generated in the latter a taste and aroma recalling the taste and aroma of the original tobacco from which the pure cultures had been in the first instance procured. Thus it may be possible in the future to raise the quality of German tobacco, not, as heretofore, so much by careful culture and judicious selection of varieties, which has so far proved unsuccessful, but by inoculating pure cultures of bacteria found in some of the fine foreign tobaccos on to our own raw material, whereby similar fermentative changes may be induced

and the quality correspondingly improved. The further results promised by Suchsland will be looked for with much interest. In connection with the above experiments on the "transplantation," so to speak, of micro-organisms, it is interesting to note some results obtained lately by Nathan (*Die Bedeutung der Hefenreinheit für die Obstweinbereitung*). The amount of alcohol present in such wines as cider, currant wine, etc., is generally from 3 to 4 per cent. This small proportion is possibly in part due to the necessarily large dilution of the fruit with water, which considerably reduces the nitrogenous constituents of the "must," and also to the fact that the yeast, according to Hansen mostly present on sweet fruits is the *Saccharomyces apiculatus*, which only possesses a feeble fermentative power. Experiments were made to see whether, by increasing the nitrogenous constituents of the "must," and introducing a pure cultivation of a vigorous wine yeast, the yield of alcohol would be greater. It was found that by adding a small amount of nitrogenous material, such as 0.15 gram ammonium chloride, and 5 cubic centimetres of wine yeast per litre to the "apple-must" (which was the fruit selected) 2 per cent more alcohol was obtained, and not only was this the case, but this cider possessed a finer and more vinous taste than that untreated, or which had only received an additional supply of ammonium chloride without the wine yeast. Kosutany in a paper published in the *Landw. Versuchsstationen*, 1892, has recorded the results of his investigations on the behaviour of certain species of wine yeast. He states that not only is the percentage of alcohol yielded very different with particular yeasts, but that also the taste, smell, and bouquet of the wine inoculated with special cultures were distinctly different according to the variety of yeast employed. It is hoped that, as in the case of tobacco so with wine, it may be possible to raise the quality by the judicious transplanting of bacteria obtained from finer brands.

THE additions to the Zoological Society's Gardens during the past week include a — Squirrel (*Sciurus* —) from China, presented by Mr. Julius Neumann, a Crowned Hawk Eagle (*Spizaetus coronatus*) from South Africa, presented by Mr. T. H. Mills, a Macaque Monkey (*Macacus cynomolgus* ?) from India, deposited, three Sulphury Tyrants (*Ptilangus sulphuratus*) from South America, six common Widgeons (*Marica penelope*, 3 ♂, 3 ♀), four common Pintails (*Dafila acuta*, 2 ♂, 2 ♀), two Pintailed Sand Grouse (*Pterocles alchata*, ♂ ♀) European, purchased.

#### OUR ASTRONOMICAL COLUMN

JUPITER'S FIFTH SATELLITE.—Mr. A. A. Common, in a letter to the *Times* for December 28, writes with respect to the fifth satellite of Jupiter:—

"This extremely difficult telescopic object discovered by Prof. Barnard last September at the Lick Observatory has been looked for with the 5 ft reflector on several occasions. On October 18 and on December 13 it was pretty certainly seen, by me on the first occasion, and by Mr. Albert Taylor on the second. The last two evenings (Sunday and Monday) have been very fine, and on each, between five and six o'clock, the satellite has been seen with certainty by Mr. Taylor and in glimpses by me.

"The brightness seems less than that assigned to it by Prof. Barnard, but this may be due to the very much better sky they enjoy at Mount Hamilton, the glare from Jupiter would be with them very much less, so that they would have the planet on a much darker background, and it would appear brighter than it does here.

"I have not heard of any other observations having been made out of America."

COMET BROOKS (NOVEMBER 1890, 1892).—*Edinburgh Circular*, No. 36, gives the ephemeris of this comet, from which the following extract is made. This comet, according to Ber-

berich's computations, will soon commence to decrease in brightness

THE MARKINGS ON MARS —In No. 25 of the Publications of the Astronomical Society of the Pacific, Mr. Schaeferle has a preliminary note on the question as to whether the darker and the brighter areas on Mars are water and land or *vice versa*. Having observed the planet from June 11 up to the present time he has been led to the conclusion opposite to that of Schiaparelli, Flammarion, and other observers, and considers that after all the dark portions should be considered as land and the bright as water. In raising such a question as this Mr. Schaeferle has been very reserved, for should his opinion receive due attention, as of course it should do, and be corroborated, the planet's surface will be looked upon in quite a different light than formerly. In this note he sets forth a few of his reasons for coming to such a conclusion, and it may interest many of our readers if we state some of them briefly. If the dark markings be taken as land, would not the irregular gradations of shade be more naturally expected than if we consider them as fixed surface features? "Light reflected from a spherical surface of water in a slight state of agitation would vary uniformly in intensity. At opposition, the centre of the planet would, for a water surface, appear brightest. Observations show that within a certain distance from the edge of Mars there is a gradual increase in the steady lustre of the brighter areas towards the centre of the planet." Assuming these dark areas to be water, then they should thus be least dark near the centre, which is somewhat contrary to observation. With reference to the "canals," he says that they on this hypothesis "correspond to the ridges of mountains which are almost wholly immersed in water," while with regard to their observed doubling he remarks that they can be explained as "representing parallel ridges of which our own earth furnishes examples." As a concluding argument he takes an observed terrestrial observation, the view of the lower end of San Francisco Bay from Mount Hamilton, San Francisco being fifty miles away. At all hours of the day, he says, "the surface of San Francisco Bay (as seen from the top of Mount Hamilton) is much brighter than the neighbouring valley and mountains at the same distance." He further adds that the line of sight makes an angle of more than 87° with the normal to the surface of the bay, while the observer's position "varies all the way from being nearly in a direct line between the bay and the sun to the position in which the sun is nearly in the direction of the bay."

THE LICK OBSERVATORY —Miss Millicent W. Shinn is the writer of a very interesting pamphlet on the history of the Lick Astronomical Department of the University of California. In these few pages she brings together much with regard to the early events connected with the founding of the giant refractor that is not generally known. For instance, it is curious to read how Mr. Lick wished to be immortalized by leaving bequests for costly statues of himself and his family, and when urged that such statues would be preserved for all time, was answered by Mr. Staples that "more likely we shall get into a war with Russia or somebody, and they will come round here

with warships and smash the statues to pieces in bombarding the city." Mr. Lick was so struck by this, that he asked, "What shall I do with the money, then?" How this question was answered is now well known, and astronomical science was presented with the finest object-glass that was ever made.

Mr. Lick's deed prescribed that the Observatory should be "made useful in promoting science," and up to the present these words have been carried out to the letter. The big telescope has not been preserved for one side of astronomical science, but has dived into all branches, as every astronomer is aware. Not only have minute double stars been observed and measured, but the spectroscope has been employed, from which excellent results have been published, while lunar photograph, equalling, if not excelling, those that had been previously obtained have brought to light much to set us thinking about Jupiter's fifth moon is perhaps the latest arrival of which we have heard, and this, following just 300 years after Galileo's discovery, would alone render the Observatory famous. That the Lick Astronomical Department, during the few years of its existence, has done an immense amount of good work, especially when one takes into account the comparatively small staff on hand, cannot be denied, and we hope the day will come when the number of such telescopes will be increased, for the ever-opening fields of research point out how necessary they are.

WASHINGTON MAGNETIC OBSERVATIONS —The United States Naval Observatory has quite recently published their magnetic observations that were made during the past year, prepared on the same plan as that for 1889-90. The observations for 1891, as Mr. Hoogewerff (who was in charge for the greater part of the year) informs us, are better than those of former years, owing to the fact that the reductions took place at no very distant dates from the observations, the experience thus gained helping to correct and guard against conditions which might have tended to give rise to errors. The introduction contains a description of the buildings, methods of observing, together with the personnel during the year, concluding with a description of the tabular results. The tabular results, as usual, show the mean hourly readings for the elements for each month, Table I containing the mean values for the four years 1888-91.

Simultaneous with this volume was also issued the meteorological observations and results for the year 1888.

### GEOGRAPHICAL NOTES.

A SPECIAL number of the *Mouvement Géographique* is devoted to a series of important despatches from M. Alexandre Delcommune, chief of the Lomami expedition of the Katanga Company. Entering the Lomami from the Congo, the party left the river on May 13, 1891, and explored the entirely untraversed territory between its upper valley river and that of the Sankuru as far as 8° S. Thence they turned eastward and reached Lake Kassali on the Lualaba, and struck south through Garenganze's country to Bunkela. Making a circuit through Katanga and westward, they found the Lualaba near its source, and following it for 200 kilometres, discovered a grand gorge at Nzole, where the river flowed in a succession of wild cataracts between cliffs nearly a thousand feet high, and not more than forty yards apart. From the rapids they returned to Bunkela, travelled north eastward over the plateau, crossing the Luapula at its outflow from Lake Moero, and ultimately reached Lake Tanganyika. The difficulties overcome were very great, and the sufferings of the caravan have rarely been surpassed even in the grimmest records of African travel.

AMONGST the English travellers who have recently arrived in London are Mr. Selous, the famous South African hunter, and Mr. Conway, who has probably climbed higher than any other European in the Karakoram range. Both gentlemen will read papers to the Royal Geographical Society early next year.

THE arrangements for the Royal Geographical Society's evening meetings after Christmas are unusually varied. Mr. Hume will describe his journey up the Burram river in Sarawak to Mount Dulit, at the first meeting in January. The second meeting will be devoted to the Island of Yezo, when Prof. Milne and Mr. Savage Lander will read papers. Papers by Captain Bower and the American traveller Mr. Rockhill, on Tibet, will be given later, and Lieutenant Peary will personally describe

his experiences in the north of Greenland. In March Prof Bonny will lecture on the action of ice in producing geographical forms, and there will be other papers dealing with the scientific basis of geography.

THE death of Cardinal Lavigerie on November 24 removed one of the most powerful personages who have recently influenced the geography of Africa. It is very largely on account of his labours that the French Roman Catholic missions have played so conspicuous a part in combating the slave trade, and to him also is due the formation of a much-needed Belgian Anti-slavery Society.

THE British Government having decided to relieve the East African Company from the responsibility of occupying Uganda, an Imperial commission, under the charge of Sir Gerald Portal, will set out from Mombasa as soon as it can be got ready to take over the administration of the country. Another fact of some interest is the revival by Mr Cecil Rhodes of the idea of exploring Africa by telegraph. He proposes to lay down a line from the Cape to Uganda, and ultimately to extend it to Egypt. In a few months the South African Company's wires will have reached the mission station of Blantyre north of the Zambesi, and there are no serious physical difficulties in continuing the line to the head waters of the Nile. The effect on the exploration of Africa will be enormous, not the least important result being the possibility of arriving at the true longitudes of places in the interior of the continent.

### DEW AND FROST

A PAMPHLET recording some interesting "Observations on Dew and Frost," by the Hon. R. Russell, has just been published by Mr Edward Stanford. We reprint Mr Russell's "Summary of Results" —

The observations were begun with the object of verifying the commonly received theory of dew, and with a strong feeling that the results obtained by Col. Bailegey, described in the *Proceedings of the Royal Meteorological Society* for April, 1891, opposed as they were in some measure to the accepted teaching on the subject, would not be corroborated. When, after exposing inverted glass tumblers and pans on grass and bare earth in the summer of 1891, dew was often found in surprising amount in the interior, I attributed the deposit to vaporous air which might have entered under the rim and parted with its moisture in the calm of the inclosed space. But when it was found that a tumbler pressed down into dry earth, and other vessels admitting little air from outside, were considerably bedewed in the interior, and when, further, similar vessels inverted on earthenware or metal plates were found to be very slightly or not at all bedewed inside, it became more probable that the vapour condensed in the interior of vessels over grass and garden earth had proceeded from the earth beneath. Next, it was found that china plates, admitting a flow of air between their lower surfaces and the ground, were more heavily bedewed on their lower than on their upper surfaces, and that a cylinder of glass was most bedewed on the lower outer and upper inner surfaces. These observations confirmed the suspicion that the dew on the inside of the hollow vessels was derived from the ground. It was for a long time a matter of doubt and difficulty that vessels inverted over dry, dusty earth and dry turf were found copiously bedewed within on the morning following exposure. On many mornings the amount of dew in the interior increased in some proportion to the precautions taken to exclude free air, and it seemed highly improbable that moist air penetrated, without depositing on its way much of its moisture, either through the dusty earth banked round the edges of the vessel, and exposed to the sky, or else through the dusty covering of earth below the vessel from lower layers.

In December, 1891, during hard frost and very fine weather, with calm or very light airs, the ground being frozen hard, leaves of bushes, ferns, &c., were seen to be frosted both on their upper and lower sides, though much less on the lower sides facing the bare ground than on the upper sides facing the open sky. Where thick fern grew between the observed leaves and the ground, there was no rime on the lower sides of the overhanging ferns or leaves. This seemed to show that the rime on the lower sides of ferns was due to exhalation from the ground, for the interruption of radiant heat from the earth by dry litter would rather favour than reduce the frosting of the under sides. Live leaves on bushes, and dead leaves on the ground, were whitened with

frost on their upper sides, and had a thin film or coat of transparent ice on their lower sides. Leaves and sticks on the ground were less frosted on the sides facing the ground than on the top. Thick planks between a few inches and one foot above the ground were about a third as much frosted on the lower as on the upper sides. Considering that the upper side of a plank 1 inch thick would fall to a considerably lower temperature by radiation than the lower side, it may be supposed that the deposition would have been largest on the lower side if they had been at the same temperature. That much frost came from the air independently of the ground, was shown by the white roofs 12 feet above the surface of the earth. On the other hand the grass was much more heavily frosted. Moreover, tumblers inverted and pressed down on dry, hard, bare earth, on sand, and on hard turf, were moderately frosted inside, besides being thickly frosted outside. The indications, on the whole, seemed to resemble those of the previous June, but the vapour condensation attributable to exhalation from the earth bore a much smaller proportion to the total deposit than in the case of dew on interior surfaces observed in summer.

Boards, tiles, and stones (sandstone) in heaps were frosted on the top, and especially in cracks and indentations of the top surface, but not in the interstices between the separate pieces. Stones on the ground were sometimes not frosted at all on the top, but much on the parts against the sandy earth, and where bedded in the ground.

Further experiments in May and in the summer months of 1892 gave strong confirmation of the evidence that much dew and frost are caused by exhalation of vapour from the earth, even in dry weather.

The facts that—

- (1) A large quantity of dew was invariably found on clear nights in the interior of closed vessels over grass and sand.
- (2) Very little or no dew was found in the interior of vessels inverted over plates on the ground.
- (3) More dew was found on the lower side of a square, slightly raised, china plate over grass or sand than on the lower side of a similar plate placed upon the first.
- (4) The lower sides of stones, slates, and paper on grass or sand, were much more dewed than the upper sides. The flat wooden back of the minimum thermometer on clear evenings when lying on earth, sand, or grass was almost invariably wet before the upper surface.
- (5) The lower side of plates of glass, 1 or 2 in. above grass, were as much or more bedewed than the upper sides.
- (6) Leaves of bushes, leaves lying on the ground, and blades of grass were about equally bedewed on both sides.
- (7) The interior of closed vessels inverted on the grass and covered with two other inverted vessels of badly-conducting substance was thickly bedewed, and the grass in the three circular inclosures also thickly bedewed.
- (8) The deposit of dew on the interior of closed vessels inverted over dry garden earth was much less than over sand or turf, although the powdery condition of the earth in the morning showed that no deposit from the air had taken place on its surface during the night.
- (9) Usually a greater amount of dew was deposited in the interior of vessels when the earth was moist at a little depth below the surface than when the earth was at its driest.
- (10) The temperature of the space under a glass plate or other object suspended near the surface of the ground was higher than that of the upper surface of the object, and, nevertheless, a cloudy film was produced first on the lower surface, —amounted to a proof that a large part of the dew formed is derived from vapour from the earth.

Moreover, the large difference often observed between the quantity of dew deposited in the interior of a vessel inclosing a plant, and the quantity of an empty vessel, proved that much dew may be derived from the earth through plants.

Drinking glasses inverted over grassy turf, and over turf close by, from which the grass was removed, showed a similar excess of deposit on the glasses inclosing grass. More vapour was condensed on plates suspended over grass than over bare earth. In these cases the conditions are somewhat artificial, and the grass, which was covered by a suspended plate or inclosed by a glass, would be warmer than if the exposure to the sky were free, but the disturbance thus caused would tell as much against as in favour of deposition on the interior surface. It may be objected that the air in and above the grass would be colder, owing to the radiating grass, than over the bare spot, and that

therefore more dew would be deposited from the air, but this objection would scarcely be valid where a small plant was inclosed on bare earth and the deposition on the interior of the glass compared with that on a glass not inclosing a plant.

Recent investigations have proved the evaporation from plants to be very large, and since evaporation proceeds by night as well as by day, there can be no reason why a moderate proportion of the dew deposited on the surface of blades of grass and on leaves of plants generally should not be derived from the vapour which they exhale. The fact that an equal quantity of dew is deposited on glass, china, painted wood, &c., exposed to the sky to that deposited on grass, may seem to minimize the influence of plant exhalation, but we must remember that the whole of the stratum of air near the ground is rendered more vaporous by these exhalations, and that therefore the dew point is sooner reached on the surface of any body exposed to the sky in the midst of vegetation than on bare open ground. Moreover, the thickness of the substance prevents earth heat from much affecting the upper surface. The effect of grass in promoting dew formation is owing—(1) To its radiative power cooling its surface below the dew point. (2) To the consequent cooling of the stratum of air in and over the grass to a point much below that of the air a few feet higher. (3) To the obstruction offered by the grass to any light air or breeze on a nearly calm night, and the consequent settling down, without much disturbance, of a cold heavy stratum. (4) To the prevention by the grassy covering of the drying up process by sun and wind which takes place on bare ground, and to the moist earth which therefore exists under grass near the surface even in dry weather. (5) To the exhalation of vapour from the grass.

The realization of these causes explained what was always, previous to these observations, a difficulty to me, the almost entire absence of dew on heather and dry fern in the summer. Even after heavy dews, heather was invariably found perfectly dry. In fine, calm winter weather, with white frost, heather may be a good deal whitened, and the frost is then derived largely from the open air. Wood, being a good radiator and bad conductor, is heavily bedewed and frosted.

Stones, whether of sandy composition and appearance, or of close grain like flint, pebbles, and slate, are not often visibly bedewed or frosted on the top on clear nights. On their surfaces, touching or very close to the ground, they are heavily bedewed and frosted. A moderate radiative power, their usual situation removed from grass and vegetation, and in the case of the close grained stones, a conductive power greater than that of leaves, grass, and wood, though less than that of metals, prevent the deposition of much atmospheric moisture on their exposed sides. But when air highly charged with vapour impinges on them in a confined space, as on their lower sides, condensation readily takes place, just as it will take place when any substance, even polished metal, is held above the spout of a kettle of boiling water. It is apparent that since stones act as condensers to the vapour constantly arising from the earth, and since the heat of the sun and temperature of the air by day only slightly raise the temperature of the earth immediately beneath a large stone, while the radiation of heat from the stone and low air temperature of the night cause the lower side of the stone to be very cold at night, a rather large amount of moisture must be deposited on its lower surface in every twenty-four hours, and the ground on which it rests must in our climate remain always very moist. The space between the stone and the ground consequently becomes the abode of many insects which live well in damp and darkness.

Occasional observation of the distribution of dew, without careful comparison with the state of the weather, gives an impression of capriciousness which only continuous records comprising various conditions can remove.

Deposition is generally favoured by a humid air, and therefore in this country by southwesterly and westerly winds, which bring over the land the vapour derived from evaporation of the Atlantic Ocean. A smaller fall of temperature by radiation brings about condensation, and there is less tendency in any deposit to evaporate than in a drier air. Radiation may produce a greater fall of temperature in dry air, but the distance from the dew-point is commonly too wide to compensate greater humidity with greater cooling.

Calm is also very favourable to dew-formation. It allows parcels of vapour in the air to remain sufficiently long in contact with cold radiating substances to become greatly cooled, and so to become condensed upon them, and it prevents the dispersion

of the stratum of air near the ground, which is continually cooling by contact and radiation. Thus dew goes on forming while the air falls lower and lower beyond its original dew point, and while by a very gentle movement an interchange is kept up between the warmer air touching the ground beneath the grass, and the cold air on the surface of the grass, and between differently cooled layers and portions of air above it. If the air is very humid, a very slight air or breeze is favourable to heavy deposition. On ordinary clear nights, calm and light airs allow the reduction of the lowest stratum of air to the dew point, and there is no liability to evaporation of the minute deposited particles by portions of air above the dew point being driven against them. When the air is rather dry, as often happens at night in dry summer weather, and in winter frosts, calm is frequently a necessary condition for the deposit and appearance of dew and white frost. The deposit may be observed to take place on the cessation of wind, and again, the change from calm to wind soon dries off the dew which has already formed. On other occasions, when there is a gentle air or breeze, dew and frost are deposited only in sheltered places, as on the most sheltered slopes of fields, on banks sloping to leeward, on leaves on the lee side of bushes and trees, on the lee side of mole-hills, posts, railings, and other objects. Hollows, depressions, and cracks, in paper, glass, stones, tiles, wood, and leaves, are more bedewed than flat surfaces from the same reason,—the reduction below the dew-point of air less diluted than that which is more free by currents of higher temperature and greater dryness. With a fresh west wind in a clear night, the raised and ribbed parts of leaves, &c., may be thickly bedewed and frosted, but the hollows and folds scarcely if at all less, and the sides of buds, thorns, &c., are more frosted than the points. The wind is, in fact, often sufficiently removed from the dew point to prevent deposition or continuance of moisture on all parts which are fully exposed to it. Not even free radiation to a clear sky then avails to plant frost growths upon the object whose temperature is being perpetually supplied by the forcible impact of warmer air.

Free radiation or exposed situation is, on the whole, perhaps the most effectual cause of dew on very many nights in the year. In a level country those parts of a field which are least sheltered by trees and hedges gather most dew and frost on calm nights. Similarly, those parts of any flat substance, such as a sheet of glass or paper, which have the most uninterrupted exposure to the sky are most bedewed. The tops of bushes, posts, railings, inverted drinking glasses, pans, &c., are on calm nights, and sometimes breezy nights, more bedewed than the sides. Greater cold by greater radiation in these cases produces greater deposition from the cooled air which comes in contact with the freely radiating surfaces. It must be remarked, however, that radiation from fine points, such as the tips of sharp thorns, is often not sufficient to counteract in air which is not very humid the effect of the continual impact of air above the dew-point and higher in temperature. Close to the ground the case is different, for there the temperature of the low stratum of air is lower, and usually about the dew-point, there is little movement, and vapour from the ground increases humidity, but even in this situation the points of grasses, &c., are often less bedewed than the sides.

That free radiation is by no means necessary for the formation of heavy dew on grass is proved by the experiments detailed above, made during the summer of 1892. The grass was found heavily bedewed in dry weather within three enclosures of earthenware by which radiation was arrested.

Since grass covered by hollow vessels, and the interior of hollow vessels themselves, are thickly covered with dew, it would seem likely that the grass under overhanging trees would be as thickly bedewed as the exposed grass in a field, and that the under sides of the overhanging leaves would also be wetted. This is not the case. And there are differences in the two situations sufficient to account for the absence of dew under leafy trees. In the first place, on a calm night, the air under a tree is warmer than in the open owing to radiation from the ground being arrested. Secondly, whatever vapour escapes from the earth is unable to condense on the grass which covers it, the grass being but little colder than the air and vapour. Thirdly, and herein lies the chief difference, the air under the tree moves freely and is above the dew-point, since the earth and other objects which it touches are warmer than the grass and air outside. If the air were confined in a small space, the increments of vapour issuing from the earth, and the gradual cooling of the grass under the tree and of the tree itself, might cause deposition, but air which has parted with much of its moisture outside is

constantly mixing with a considerable body of air already warmed under the sheltering canopy. Thus all objects under the tree remain above or not much below the dew point of the air which touches them. Yet, on a calm night, long grass and other substances a little raised above the ground are sometimes heavily bedewed, though largely hindered by overhanging branches from losing their heat by radiation. They often remain nearly dry till the morning hours, and then reach a temperature below the dew-point. The absence of dew under trees and bushes is, within limits, roughly proportional to the area of ground covered. A large surface of dry ground slowly parting with its heat during the night has a powerful effect in preventing condensation. Small bushes on a humid clear night are often much bedewed even on their lower leaves. On the night of October 5, 1892, both sides of the leaves of bushes in all sheltered situations were found thickly bedewed, but where leaves were either exposed to the slight breeze which was blowing, or near the wall of the house on which the sun had shone, they were dry. The warm, dry wall of a house acts a part similar to that of the earth under a tree in radiating warmth to neighbouring objects, and in warming the air by contact. The vapour emerging from earth sheltered by foliage several feet above it has time to mix well with air before coming in contact with solid objects. In the hollow vessels, and even in the space between a raised plate of glass and the earth, the vapour which rises from the earth has no time to become equally distributed in the air before meeting with substances colder than itself, in the closed vessels the initial amount of vapour is augmented so as to produce constant saturation. Objects, such as drinking glasses, raised several feet above the grass, were seldom much bedewed, and often quite dry.

The increase of pasture-land in England must have a considerable effect in increasing cold by radiation, and in diminishing the amount of vapour in the air at night by deposition on grass. The sensible moisture at night must be increased near the ground, the dew point being quickly reached on a clear night over grass.

The large quantity of dew found on plates and other objects over sandy ground, dry to a depth of several inches, proves the possibility of a large emanation of noxious vapours from soil containing decaying organic matter below a covering of sand. The age of parts of East Anglia and of sandy malarious districts may be thus accounted for.

Houses built on sandy ground over a damp subsoil may be considered as scarcely more wholesome than if built on the damp soil itself.

In late summer and early autumn the high temperature of the soil in comparison with the temperature of the surface and of the air near the ground at night, must have a powerful effect in the production of vaporous exhalations. The heavy rains which so often occur in October, the wettest month of the year, must co-operate with a falling air temperature in driving out air from the pores of the earth.

In nearly all the conclusions of Wells, as stated in his admirable "Essay on Dew," my observations lead me to concur. He found that calm is favourable to the precipitation of dew, that if, in the course of the night, the weather, from being calm and serene, became windy and cloudy, not only did dew cease to form, but that which had formed either disappeared or diminished considerably, that if the clouds were high and the weather calm, dew sometimes formed to no very inconsiderable extent, that dew often forms on shaded grass even several hours before sunset, and continues to form after sunrise, that, if the weather be favourable, more dew forms a little before, and, in shaded places, a little after sunrise, than at any other time, that on substances elevated a few feet above the ground it forms much later in the evening, but continues to form as long after the rising of the sun as upon the ground, that dew is more abundant shortly after rain than during a long tract of dry weather, that dew is always very copious on those clear and calm nights which are followed by misty or foggy mornings, and also on clear mornings after cloudy nights, and generally after hot days, that more dew was formed between midnight and sunrise than between sunset and midnight, owing doubtless "to the cold of the atmosphere being greater in the latter than in the prior part of the night," that whatever diminishes the view of the sky diminishes the quantity of dew, that a substance placed on a raised board of some extent acquired more dew on a very still night than a similar substance lying on grass; that bright metals attract dew much less powerfully than other bodies, that a metal which has been purposely moistened will often become dry

though similarly exposed with bodies which are attracting dew, and that wool laid upon a metal acquires much less dew than an equal quantity laid upon grass in the immediate vicinity, that a metal plate on grass always became moist on the lower side during the night, though the upper side was often very dry, but that if the plate was elevated several feet in the air, the condition of both sides was always the same, whether dry or moist, that wool on a raised board was commonly colder than on the grass on very still nights, and that the leeward side of the board was colder than the windward, that bare gravel and garden mould were very much warmer after sunset than neighbouring grass, that on dewy nights the temperature of the earth half an inch or an inch beneath its surface was much warmer than the grass upon it, and than the air, that metal covering grass was only slightly colder than the grass covered, and this again colder than the earth, that metal thus exposed was warmer than air 4 feet above it, and much warmer than neighbouring grass, that the variety in the quantities of dew, formed upon bodies of the same kind in different situations, was occasioned by the diversity of temperature existing among them, and that on nights favourable to the production of dew, only a very small part of what occurs is owing to vapour rising from the earth.

The last of these conclusions Wells supported by the observation that the dew on the grass increased considerably about sunset, the same time at which dew began to show itself on the raised board, and by the reflection that, "though bodies situated on the ground after they have been made sufficiently cold by radiation to condense the vapour of the atmosphere will be able to retain the moisture which they acquire by condensing the vapour of the earth, yet, before this happens, the rising vapour must have been greatly diminished by the surface of the ground having become much colder." He adduced the fact that substances on the raised board attracted rather more dew throughout the night than substances lying on the grass. He admitted that all the dew on calm, cloudy nights might be attributed to condensation of the earth's vapour, since on such nights the raised board was dry.

But if the grass was moist on these calm, cloudy nights, and the moisture were owing to earth-vapour, it is only reasonable to infer that a very much larger quantity was owing to earth vapour on clear nights when radiation was comparatively free. Moreover, the fact that substances on the raised board became wetter than substances on the grass may be attributed to the non conducting wood intercepting the warmth radiated from the ground, and thus allowing a substance on the upper surface of the board to become colder than a substance on the grass. And with regard to the "rising vapour" being greatly diminished by the surface of the ground having become colder, it does not appear that such diminution actually occurs, owing possibly to the influence of the high temperature of the preceding day reaching the moist earth at a little depth below the surface about the same time. I have found the deposition of earth vapour to proceed at a rapid rate after sunrise over grass.

Wells explains with much ingenuity the reason why leaves of trees often remain dry throughout the night, while those of grass are covered with dew. But he does not, I think, attach sufficient weight to the fact which he mentions among others, that the air near the ground is near one of its sources of moisture, while the tops of trees are removed from that source. The air is both damper and colder near the ground, a stratum of cooled air rests upon warm earth emitting vapour. The tops of trees are pervaded by air which is drier and warmer, and the leaves do not allow air to rest long enough on their cooled surfaces to part with sufficient heat in order that condensation may ensue.

I have found that when the air is clear and not humid, radiation into space is often not sufficient to cause visible dew or frost except in sheltered calm places, and in the same condition of air deposition takes place more on broad surfaces than on thin shoots, threads, and points, and more on the faces than on the edges of leaves. It appears necessary that a certain stability of temperature below that of the air, and a certain protection from re-absorption by the drier portions of air which pass over, should be attained in order that dew and frost may accumulate. When, on the other hand, the air is very moist, with a tendency to mist or fog, a very large condensation takes place on exposed objects, and especially on those which are at some height above the ground, such as the branches and twigs of trees. Points, thorns, spiders' webs, and other thin filaments are then heavily bedewed. Mist or fog often follows.

When some mist has formed on such a night, there is a heavy

precipitation on trees, &c., which is increased by wind, and large drops of rain on to the ground beneath them. This condition seems best explained by Aitken's discoveries showing the possibility of a super-saturation of air when the number of dust-particles is unusually small in a mass of air which is humid and cooled to saturation. The dust particles from their minuteness, and from their inability to fall below the temperature of the air owing to the cloud canopy above, do not condense much of the vapour, and consequently any solid object of the same or slightly lower temperature brings about precipitation from the passing air, which may possibly be super saturated. A slight fall of temperature in the air, or sometime, an increase of dust particles, then produces fog. A dry fog may thus result from cold causing condensation on a very large number of dust-particles which are radiating heat rather freely, and a damp mist from partial condensation from super saturated air on a comparatively small number of dust particles not radiating freely owing to a clouded sky.

These considerations explain why a dry fog is densest in London and a wet mist densest in the country. A dry fog is the work of cold radiating particles, a wet mist is the work of cold air mixing with warm. "In a fog," says Angus Rankin, "the watery vapour in condensing has more particles to condense on, and consequently the particles of fog are smaller, and on meeting with an object with a higher temperature, instead of wetting it the object dries them up by parting with some of its heat. On the other hand, in a mist, the particles of dust, being few, have more water condensed on each, and so are larger and do not readily evaporate with small increments of heat." Yet in a damp mist the addition of a large number of dust particles, as in a town by day, scarcely increases the density of the mist. In fact, the wet mist is less dense in London than in the country, owing to the higher temperature and lower humidity of the air. Dry or radiation fogs, which cling to the ground, are the most dense in smoky places.

In fogs with frost in winter, such as have occurred several times in the last few years, I have always found the windward side of objects to be much more heavily frosted than the lee ward, and the time to attach itself most to points and edges. Trees have thus become laden with rime, even so as to break down branches, iron points of railings, splinters of wood, wires, and blades of grass have borne spikes and fern like growths an inch or more long, and heather and fern in hollows have been whitened as if with a fall of snow. In weather of this kind it is difficult to say what is dew or frost proper, and what is deposited moisture from super-saturated air and from fog. On the same night a white frost may present the characteristics of fog-deposition in a valley and of clear condensation on a neighbouring hill.

Dew and frost are in fine the result of many causes which inter operate in a complex manner. The importance of the laws of gases of the multitude of fine adaptations in the relations of vapour, air, water, earth, and plants, the importance, too, of the thermal receptivity of boundless space, gives an interest to this branch of meteorology which is second only to its beauty.

### ARBORESCENT FROST PATTERNS

PROF MELDOLA'S account of Arborescent Frost Patterns has excited a good deal of interest, and we have received many letters on the subject, some of which we have already published. To-day we give reproductions of photographs we have received from Mr J Maclear, Cranleigh. Fig 1 represents a photograph of a facsimile tracing of a "Nature print" of an ice crystallite taken by Mr. A. Anderson on a still and sunny early morning in January 1887, after a not very severe frost. The sunshine had just dried the rest of the frost off the flagstone, and left this mud and ice-crystallization, which he promptly secured on soft paper by means of a soft pad-pressure, and thus got a perfect Nature printed impression. The original (now unfortunately lost) showed an appearance of vegetable (moss) growth, even more strikingly than in this tracing from it.

With regard to Fig 2 Mr Maclear writes—"The melting ice under the dabbling pad formed a natural pigment with the

mud on the flagstone, the rest of the flagstones being perfectly dry already by the early morning sunshine."

Prof Meldola sends us the following interesting letter which he has received from Corbridge on Tyne—

"I was much interested by your note in NATURE the other day, anent the frost markings of a vegetable pattern. I have seen just the same forms several times in the north, but it is I think the least common of the patterns usually met with. I write, however, to call your attention to Figs 1 and 7 of Plate

FIG 1.—Ice crystallite, 'Nature printed' by A. Anderson, January 1887. Facsimile tracing by J. Maclear, January 1887. Size of crystal 14 inches X 13 inches.

vii, illustrating the article on Meteorology in the "Encyclopædia Metropolitana" (1845, vol 1 of plates, vol v of text). These figures are very like yours and some of the others given with them are also very interesting. I have often shown my students when out in the fields in cold weather how exactly the mud

FIG 2.—Photograph from the original "Nature print," made by Mr A. Anderson, of an ice crystallite, January 1887. Size of crystal, 10 inches X 7 inches.

and cum frost markings of the common feathery volute type imitate the so called *Canda galli* fossil fucoid (?) which is one of the most abundant objects on the surface of the carboniferous lime stone courses about here. As far as form goes they are identical, and there is no structure to be discovered in the fossil markings.

"Corbridge-on-Tyne, December 16 G. A. LEBOUR"

PROF SOLLAS writes to us—"The correspondence on this subject that has lately appeared in your columns (particularly Prof. Bonney's reference), leads me to anticipate a communication I hope shortly to present to the Royal Dublin Society on the growth of crystals. The arborescent forms assumed by ice are merely a special case of a very general problem—that of the

<sup>1</sup> Journal of the Scottish Meteorological Society. Third Series. No. viii

forms assumed by crystals under different conditions. Petrologists have long been familiar with the tendency of crystals developing in a viscid medium to excessive growth in one or more directions. Felspar is a familiar instance, the lath-like forms which it frequently assumes being due to elongation along one axis ( $x$ ), the length of prisms measured along this axis often exceeding by ten times that along the axis  $y$  or  $z$ . The cause of this need not now be discussed, it will be sufficient to add that the phenomenon is not special to felspar, but is of quite general occurrence. With this tendency is connected the origin of curvilinear forms. We may consider the molecules forming the growing face of a long prism, the spheres of influence of these lie half within and half without the substance of the crystal. Considering this influence as attractive (directly or indirectly), we may say that the attraction of the molecules leading to further deposition is one half their total attraction. If now from the face we pass to the edge between two faces at right angles, only one-quarter of the sphere will be immersed, and the attraction may be spoken of as three quarters of the whole, while if from the edge we pass to a corner, only one-eighth is immersed, and the attraction becomes seven eighths. From this it follows that growth should be more rapid at the edges than over the surface of the face, and still more rapid at the corners. In accordance with this we find young growing prisms in a viscid medium increasing so rapidly at the edges as to leave a space in and about the axis filled with the medium in a non-crystalline state. Indeed, a viscid medium is not necessary, hollow prisms are of common occurrence whenever crystallization takes place with rapidity. Further, in quite embryonic crystallites, V. gelatin figures, elongated prism-like forms, in which the four corners are produced parallel to the long axis into processes resembling spines. There is an additional reason pointed out to me by Prof. Fitzgerald why growth should be more rapid at the edges and corners than over the general surface, and that is that these parts are more exposed to molecular bombardment.

If crystals are more readily built up along edges and corners, we should expect them to be more readily unbuild in these regions, and this is in accordance with observation, the zonal felspars of igneous rocks, in the formation of which intervals of solution have alternated with periods of growth, usually present, in the outlines of each resulting envelope, rounded corners.

The influence of corners is well seen in some glassy rocks where small prisms of felspar (andesite) may be observed, with five or six slenderer but longer prisms springing from a corner in radiate divergence.

From this it is but a step to curvilinear growth. Let a prism tend to rapid rectilinear growth, and any check immediately in front will lead to a forward growth from a corner in a slightly different direction, even the competition of molecules for this centre of attraction may by overcrowding bring about this result, and thus both branching and curvilinear forms may arise. This is beautifully exemplified in the spherulites of many igneous rocks, where we find in the centre of a radiately crystallized sphere a long prism of felspar serving as a nucleus, and from the ends of this slender, almost linear, prism diverge towards a spherical surface which by repeated branching and associated curving they everywhere reach, leaving about the sides of the nucleus a spherical space almost devoid of crystal structure. The whole arrangement in median longitudinal section presents a remarkable resemblance to the lines of force as shown by iron-filings about a bar magnet.

Evidently in rapid crystallization with a tendency to linear growth, divergence may be repeated at such frequent intervals as to produce forms which to the unaided eye appear to be continuous curves.

## SOCIETIES AND ACADEMIES.

### LONDON

Mathematical Society, December 8.—Mr A. B. Kempe, F.R.S., President, in the chair.—The following communications were made.—On a theorem in differentiation, and its application to spherical harmonics, by Dr. Hobson.—On Cauchy's condensation test for the convergence of series, by Prof. M. J. M. Hill.—Cauchy's condensation test for the convergence of series is as follows.—If  $f(n)$  be positive for all values of  $n$ , and constantly decrease as  $n$  increases, then the series  $\sum f(n)$  and  $\sum a^n f(a^n)$  are both convergent or both divergent,

where  $a$  is any positive integer not less than 2. There is a clear reason why  $a$  cannot be unity, for then  $\sum a^n f(a^n) = \sum f(1)$ , which is always infinite. It is proved in Chrystal's "Algebra" that the theorem is also true if  $a$  have any positive fractional value not less than 2, see part 2, chapter xxvi, § 6, cor. 1. The proof there given when  $a$  lies between the consecutive positive integers  $p$  and  $p+1$  is based on Cauchy's proof for the two cases  $a = p$  and  $a = p+1$ . But this proof will not apply when  $1 < a < 2$ , because Cauchy's proof will not apply when  $a = 1$ . Yet it does not seem possible to assign a reason for excluding values of  $a$  between 1 and 2, for Cauchy's method appears to depend on this—viz. that for increasing values of  $n$  the expression  $f(a^n)$  occupies more and more advanced positions amongst the terms of the series  $\sum f(n)$ , but this is possible if  $1 < a < 2$ , as well as when  $a > 2$ . If  $a < 1$ , then this is no longer true. The problem then considered in this paper is so to recast the proof for fractional values of  $a$  as not to exclude the case  $1 < a < 2$ . The complete theorem will then stand thus.—If  $f(n)$  be positive for all values of  $n$ , and constantly decrease as  $n$  increases, then the series  $\sum f(n)$  and  $\sum a^n f(a^n)$  are both convergent or both divergent if  $a > 1$ . The demonstration depends on the following theorems.

I. If  $\sum a^n f(a^n)$  be convergent, then—

$$\sum_{n=1}^{\infty} f(n) < f(1) + f(t_2) + (a-1+a^{-t_2}) \left[ \sum_{n=1}^{\infty} a^n f(a^n) - \sum_{n=1}^{t_2-1} a^n f(a^n) \right]$$

where  $t_2$  is any integer so large that

$$a^{t_2+1} - a^{t_2} > 1,$$

and  $t_2$  is the greatest integer in  $a^{t_2}$ ,  $a$  being greater than 1.

II (A). If  $\sum a^n f(a^n)$  be divergent, and if  $a^n f(a^n)$  diminish as  $n$  increases beyond a certain value, then

$$\sum_{n=1}^{\infty} f(n) > f(1) + f(t_2) + (1-a^{-t_2}-a^{-t_2-1}) \left[ \sum_{n=1}^{\infty} a^n f(a^n) - \sum_{n=1}^{t_2-1} a^n f(a^n) \right]$$

II (B). If  $\sum a^n f(a^n)$  be divergent, and if  $a^n f(a^n)$  do not diminish as  $n$  increases beyond a certain value, then—

$$\sum_{n=1}^{\infty} f(n) > \sum_{n=1}^{t_2} f(n) + \sum_{n=t_2+1}^{\infty} A n^{-1},$$

where  $s$  is an integer taken large enough, and  $A$  is some finite quantity.—Additional note on secondary Lucker circles, by Mr J. Griffiths.—Notes on determinants, by Mr J. E. Campbell. In accordance with the late Prof. Smith's notation, a determinant of the  $p^{\text{th}}$  class may be written

$$|a_{ijk}|$$

The fact that a determinant of the second class (an ordinary determinant) is not altered if the vertical columns be written horizontally is expressed by the identity

$$|a_{ij}| = |a_{ji}|$$

For determinants of higher class it is known that any of the suffixes can be interchanged, except the first, and if the class be even, the first suffix can also be interchanged with any other, but for determinants of odd class this is not true. By considering a cubic determinant as an ordinary determinant in alternate numbers, the author tries to explain this essential distinction between determinants of odd and even classes. If the element  $a_{pqr} = -a_{qpr}$ , and  $a_{ppr} = 0$ , the determinant is called skew symmetrical. It is easily seen that skew symmetrical determinants of even class and odd degree vanish identically. This is analogous to the well known theorem in ordinary determinants, but there is no corresponding analogue to the theorem that skew symmetrical determinants of the second class and even

degree are perfect squares. The reasoning which establishes these propositions does not apply to skew symmetrical determinants of odd class. By a different method it is shown that they vanish identically whether the class be even or odd. It is next shown that if we form any determinant of even class  $2p$  from  $2p$  ordinary determinants, in a manner analogous to that in the rule for the multiplication of two ordinary determinants, the determinant so formed is the product of the  $2p$  determinants, and if any determinant of odd class  $2p+1$  is formed from  $2p+1$  ordinary determinants, the determinant so formed is the product of the last  $2p$  of these ordinary determinants into the first taken, with all its signs positive. A somewhat similar result is shown to hold for determinants of alternate numbers. As an application, let

$$s = \frac{a_1}{(x-a_1)}(y-\beta_1) + \dots + \frac{a_n}{(x-a_n)}(y-\beta_n),$$

and let  $(p, q)$  denote

$$\frac{d^p}{dx^p} \frac{d^q}{dy^q} s$$

By multiplying the arrays

$$\begin{vmatrix} a_1 \\ x-a_1 \\ a_1 \\ (x-a_1)^2 \end{vmatrix} \quad \begin{vmatrix} 1 \\ y-\beta_1 \\ 1 \\ (y-\beta_1)^2 \end{vmatrix}$$

we get

$$\begin{vmatrix} (0,0), & (0,1) \\ (1,0), & (1,1) \end{vmatrix} = \sum \frac{a_p a_q (a_p - a_q) (\beta_p - \beta_q)}{(x-a_p)^2 (x-a_q)^2 (x-a_p)^2 (y-\beta_q)^2}$$

Suppose, now,  $n=1$ , we get that the primitive of

$$\begin{vmatrix} (00), & (01) \\ (10), & (11) \end{vmatrix} \text{ is } s = \frac{a_1}{(x-a_1)}(y-\beta_1)$$

Similarly, by multiplying,

$$\begin{vmatrix} a_1 \\ (x-a_1) \\ a_1 \\ (x-a_1)^2 \\ a_1 \\ (x-a_1)^3 \end{vmatrix} \quad \begin{vmatrix} 1 \\ y-\beta_1 \\ 1 \\ (y-\beta_1)^2 \\ 1 \\ (y-\beta_1)^3 \end{vmatrix}$$

we get that the primitive of

$$\begin{vmatrix} (00), & (01), & (02) \\ (10), & (11), & (12) \\ (20), & (21), & (22) \end{vmatrix} = 0,$$

is

$$s = \frac{a_1}{(x-a_1)}(y-\beta_1) + \frac{a_2}{(x-a_2)}(y-\beta_2)$$

Similar primitives are obtained for differential equations, which are in the form of determinants of higher class. A further application is obtained by taking powers of different invariance symbols, of which (123) is the simplest for the ternary quantic. The resulting invariants are seen to be determinants of some even class. A geometrical note, by Mr R. Tucker. —The President (Major MacMahon, F.R.S., in the chair) made an impromptu communication of a problem, the solution of which he thought would be subsidiary to the sought-for solution of the "stamp folding" problem.

Linnean Society, December 15. —Prof. Stewart, President, in the chair. —The President announced the recent death of Mr H. T. Stanton, a Fellow and former Vice-President of the Society, and of European reputation amongst entomologists, by whom his loss would be widely felt. —Mr. D. Morris exhibited a series of botanical photographs from the west coast of Africa, and gave some interesting details about the appearance and mode of growth of some of the more remarkable forest trees and plants of that region. —The Secretary exhibited a large collection of photographs of Lichens, very neatly mounted and labelled, which had been recently presented to the Society by Prof. Arnold, of Munich. —On behalf of Mr. George Swainson, of St. Anne-on-Sea, Lancashire, Mr. A. R. Hammond exhibited an aquatic dipterous larva, belonging probably to the genus *Dixa*, of which by means of the oxyhydrogen lantern, with microscopic attachment, a good figure was projected on the screen. He

referred to the different views which prevailed concerning the dorsal and ventral aspects of this larva, and pointed out that the tail plates possessed features which in allied forms were characteristic not so much of the larval as of the pupal stage. —A paper was then read by Dr. Maxwell T. Masters, F.R.S., on the classification and geographical distribution of the *Zaraxae* and *Conifera*, his remarks being illustrated by a specially prepared map, lent by Mr. C. B. Clarke, and by specimens of the fruit and leaves of some of the more notable forms. —Mr. George Brook followed with a paper on the affinities of *Madiepora*, and here again, by means of the oxyhydrogen lantern, an excellent series of coral sections was projected, which illustrated very clearly the author's remarks on comparative structure. —A short note on the abnormal form of the lens in the eyes of an albino rat, by Prof. R. J. Anderson, was read on his behalf by the Secretary. The meeting then adjourned to January 19, 1893.

Zoological Society, December 6. —Dr. St. George Mivart, F.R.S., Vice-president, in the chair. —The Secretary read a report on the additions that had been made to the Society's menagerie during the month of November 1892. —Dr. Hickson read a paper entitled "A Revision of the Genera of the *Alcyonaria Stolonifera*, with a description of one new genus and several new species." The author commenced by stating the grounds upon which it might be considered desirable to retain the suborder Stolonifera, and criticized the views of those who place these Alcyonarians in the suborder Alcyonida. Of the genera that had already been proposed only four could now be retained, namely, *Fubispora*, *Clavularia*, *Cornularia*, and *Symphodium*, and the author proposed to add one more, namely, *Stereosoma*. The genera *Sarcodictyon*, *Rhizoxenia*, *Cornulariella*, *Antheia*, and *Gymnosarca* must be abandoned, and the species incorporated in the other genera. A description was then given of the new genus *Stereosoma*, a form found on the coast of North Celebes, distinguished from all other Stolonifera by certain characters of its tentacles and by the absolute non-retractability of its polypes. Several new species of *Clavularia* were then described from North Celebes, Diego Garcia, and Australia. This was followed by a summary of all the species of the genus known to science. —Mr. F. E. Beddard, F.R.S., read a description of the convolutions of the cerebral hemispheres in certain rodents. The paper referred chiefly to *Dasyprocta Catagenys*, *Lagostomus*, *Hydrochirus*, and *Dolichotis*, being the genera of rodents in which the brains show the greatest development of convolutions. —A communication was read from Prof. Collett, containing a description of a new monkey from Sumatra, for which he proposed the name *Semnopithecus thomasi*. —Mr. H. J. Elwes read the second portion of an account of the butterflies collected by Mr. W. Doherty in the Naga and Karen Hills and in Perak.

#### PARIS

Academy of Sciences, December 19. —Annual Public Meeting. —The President, M. d'Abbadie, gave a brief survey of the life and work of those lost to the Academy by death during the year. Among these were the following members: M. D. A. Richet, distinguished for his medical discoveries; M. de Quatrefages de Bréau, the naturalist; M. Julien de la Gravière, Vice Admiral under the Empire; M. Pierre Ossian Bonnet, geometrician; Admiral Mouchez, late Director of the Paris Observatory. Foreign Associate Sir G. B. Airy. *Académie des Sciences*. —M. Lalanne. Correspondents MM. Gilbert, Abria and Adams. The prizes were awarded as follows: The Grand Prize of the mathematical sciences to M. Hadamard for his solution of the problem of determining the number of primary numbers inferior to a given quantity. One Prix Bordin to M. Gabriel Koenigs for his solution of a problem concerning geodesic lines, another to M. Humbert for his work on hyper-elliptic surfaces. The Prix Poncelet to the builders of the Forth Bridge, Sir John Fowler, and Sir Benjamin Baker, the Extra Prize of 6000 francs to M. Hédouin for his work on the Channel currents; the Prix Montyon to M. N. I. Raffard, civil engineer, the Prix Plumet to M. Augustin Norman, for his geometry of ships. In Astronomy, the Prix Lalande was doubled, and awarded to Mr. Barnard and Mr. Max Wolf; the Prix Darboux to M. Radau for his work on lunar inequalities of long period caused by planets, the Prix Valz to M. Puisseux for his researches on the equatorial cloud and other instruments; the Prix Janssen to M. Lacchini for his solar work. Statistics: The Prix Montyon to MM. M.

Bastie and J. Dardignac for works on the population of France and hygienic statistics respectively. Chemistry: The Prix Jecker to M. Bouchardat for his researches on the terephene carbon compounds. Mineralogy: The Prix Vaillant to M. Lacroix for his work on the application of optical characters to the determination of rocks and mineral species. Botany: The Prix Desmazieres to M. Pierre Viala for his "Maladies de la Vigne", the Prix Montagne—1000 francs to M. l'Abbé Hue, and 500 francs to Dr. F. Xavier Gillot for their mycological researches, the Prix de la Fins Mélicocq to M. Mischel for his "Botanic Geography of Northern France." Medicine and Surgery: Prix Montyon—one to MM. Farabeuf and Varnier for work on obstetric medicine, another to M. Javal for ophthalmometry, a third to M. Lucas Champonnière for his work on hernia, the Prix Barbier was shared between M. Laborde ("Death by Chloroform") and MM. Cadéac and Albin Meunier ("Alcoholism," &c.), the Prix Bellion to Dr. Theodore Cottl for his work on "The Education of the Senses", the Prix Lallemand was shared between M. Binet ("Les Altérations de la Personnalité") and M. Durand ("Les Origines Animales de l'Homme"). Physiology: The Prix Montyon to M. Hedon (diabetes) and M. Cornevin (breeding of domestic animals), the Prix Pourat to M. H. Roger for his researches on the inhibitory power of the nervous shock. Physical Geography: the Prix Gay to M. Moureaux (distribution of magnetic elements in France). General Prizes: Prix Montyon, for improvements in unhealthy industries, to M. L. Guérault (crystal cutting), the Prix Delalande Guérineau, to M. Georges Rolland for his work on the Algerian Sahara, the Prix Jérôme Pontu, to M. Le Châtelier for his researches on dissociation and chemical equilibrium, the Prix Leconte (50,000 frs.) to M. Villemain for his demonstration of the specific nature and the transmissibility of tuberculosis. The *Comptes rendus* contains a complete list of the prizes to be awarded in the next few years.

#### BERLIN

Physical Society November 18.—Prof. Du Bois Reymond, President, in the chair.—Prof. Neesen gave an account of experiments made with a view to the photographic recording of the oscillation of projectiles. He employed hollow projectiles in whose interior was placed a sensitive plate, illuminated by sunlight through a small opening. During its rotary flight the ray of light described curves on the plate from whose position, taken in conjunction with that of the sun, the oscillation of the axis and point of the projectile would be calculated. The results obtained showed that both the axis and point perform oscillatory movements during the flight which are very different from those usually believed to take place. In order to study these more accurately, Prof. Neesen is busy with the construction of some arrangement which may admit of the introduction into the projectiles of sensitive plates which shall not participate in the rotary motion.

December 2.—Prof. Du Bois Reymond, President, in the chair.—Dr. Du Bois gave an account of experiments made by Mr. Shea in Berlin on the refraction of light in metals, and in connection with this referred to a theoretical treatise which he had recently published on the same subject in conjunction with Dr. Rubens.

Physiological Society, November 25.—Prof. Du Bois Reymond, President, in the chair.—Dr. Treitel gave an account of observations he had made on two snails enclosed in air-tight glass vessels. Dr. Ad. Baginski gave an account of a very fatal epidemic among rabbits in the same hutch, in which a post-mortem examination of the dead animal showed a serious affection of the liver and intestinal mucous membrane. The liver was filled with cysts of various sizes, in which, together with coecidium, some very remarkable growths were found, which led to very marked changes of the epithelial cells.—Dr. Rawitz made a short preliminary statement of observations on *Annullata* made during his stay at the biological station of Ravigno, on the coast of the Adriatic. While one species was found to be extremely sensitive to light, and to draw in its tentacles at once when shaded, another closely related species was quite unresponsive, while, on the other hand, it reacted immediately to the slightest touch. The first species was much less sensitive to touch.

#### AMSTERDAM

Royal Academy of Sciences, October 29.—Prof. van de Sande Bakhuyzen in the chair.—Prof. Engelmann spoke (1) on

the influence of central and reflected irritation of the nervus opticus on the movement of the cones of the retina, and (2) on the theory of the contraction of muscles.—Prof. Schoute proved the following theorem.—If  $\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1$  is the equation of a given ellipse, E, and  $f(x, y)$  contains the terms of the  $n$ th order of the equation of a curve C<sup>n</sup> with reference to the same axes. The sum A of the eccentric anomalies  $a_n$  of the  $2n$  points S<sub>1</sub> common to E and C<sup>n</sup> is determined by the relation

$$e^{iA} = \frac{f(a, ib)}{f(a, -ib)}$$

He indicated several peculiar cases of this general theorem.—Prof. Kamerlingh Onnes communicated some measurements, by Mr. Leeman, relating to Kerr's phenomenon when reflection takes place at the pole of a cobalt magnet. The constancy of the difference of phase  $\delta$ , discovered by Dr. Sisingh was confirmed. The measurements agree with the theory of Goldhammer, contrary to that of Drude. Mr. Leeman finds a magneto-optic dispersion in  $\delta$ .

November 26.—Prof. van de Sande Bakhuyzen in the chair.—Prof. Schoute continued his communication of October 29, on a general theorem in the theory of plane curves, and corrected a theorem of Liguerie.—Prof. Lorentz dealt with the relative motion of the earth and the luminiferous aether.—Prof. Kamerlingh Onnes spoke of measures on the relation of spark length and difference of potential made by Dr. Bongesius at Groningen with a double bifilar electrometer of his own construction. The differences hitherto found are explained by a correction for pressure and temperature having been omitted. Discharge between two concentric cylinders depends, as Gaugain stated, on the density of the inner one only. Proving glow discharge on the inner one of two concentric cylinders proves successful in maintaining constant high potentials.

## SCIENTIFIC WORTHIES

## XXVIII—SIR ARCHIBALD GEIKIE

SOME MONTHS ago the British Association for the Advancement of Science was holding its annual meeting at Edinburgh under the presidency of Sir Archibald Geikie, F.R.S., Director-General of the Geological Survey of the United Kingdom.

It may well be said that a more appropriate choice could hardly have been made by the Council of the learned Association. Not only is Sir Archibald a thorough Scot, born and educated in Scotland, where he fulfilled for many years the most important duties as a member of the geological staff, and later as a professor in the University of Edinburgh, but, having long been engaged in the supervision of the Scottish Survey, he mapped with his own hand many hundreds of square miles of country, and through the entire scenery of Scotland there is not a single point with the peculiarities of which he did not make himself thoroughly familiar. His knowledge of the ground is not at all restricted to geological relations. In Sir Archibald the qualities of the geologist are combined with those of the enthusiastic lover of landscape, and his able pencil excels in drawing original sketches in which the outlines, peculiar shades, and, one might say, the general spirit of the scenery are fixed with the most striking accuracy. Obviously, therefore he was the right man to be placed at the head of the Edinburgh meeting, which many prominent foreign investigators attended in the hope of afterwards travelling, both as tourists and as men of science, through the most interesting fields of the Highlands. Nobody could have been better fitted to introduce them to the country. When putting Sir Archibald in the chair at Edinburgh, the British Association not only did due justice to one of the most distinguished sons of "modern Athens," it also took the best course to secure from foreign guests the fullest recognition of the various merits of Scotland.

Sir Archibald Geikie was born at Edinburgh in 1838. We learn from a notice in the *Mining Journal* that he was educated at the Royal High School and at the Edinburgh University. When he was only twenty years old he became an assistant on the Geological Survey for Scotland, and proved so able that in 1867, when the Scottish branch of the Survey was made a separate establishment, Sir Roderick Murchison deemed he could not do better than confer the directorial powers on the young assistant whom he had appreciated at work. Four years later, the chair of Geology and Mineralogy at the University having been founded by Sir Roderick with a concurrent endowment by the Crown, Archibald Geikie was invested with the new professorship, which he resigned only at the beginning of 1881, when he was appointed to succeed Sir Andrew C. Ramsay as Director-General of the Geological Survey of the United Kingdom, and Director of the Museum of Practical Geology in Jernyn Street.

That the new Director had not disappointed the hopes he had excited, appeared with sufficient clearness when,

some time ago, the Queen conferred on him the honour of knighthood. Now it is our duty to note the chief features of his activity, and to state what personal part Sir Archibald Geikie has played in the recent progress of science. It is scarcely necessary to say that his geological achievements are too important to be conveniently reviewed in a few lines. Nevertheless we shall try to give a general idea of the prominent results to which his name must be attached.

Early appointed, as he was, as an officer of Scotland's Survey, he had, from the beginning, to deal with the most puzzling problems involved in the stratigraphy of the "Highlands." The case was a very difficult one, and gave rise to much controversy between Sir Roderick Murchison and many other geologists, among whom it will be sufficient to quote the respected name of Nicol. As in the Highlands gneisses and ordinary crystalline schists were seen resting, with apparent conformity, on Silurian strata, it had been admitted by Murchison that the sequence was a normal one. Therefore the crystalline schists had to be regarded, in spite of their Archæan appearance, as metamorphosed Silurian deposits. Such an assumption had a considerable bearing on other geological problems, as it rendered highly probable the theory that the so-called primitive gneisses were altered sediments, and had nothing to do with the early crust of the molten globe.

That Sir Archibald should at first have taken his Director's side is not at all surprising. But he was never quite satisfied, and his love of truth led him, as soon as he was in a position to do so, to undertake a detailed review of the facts. Since the discovery of Silurian fossils in the rocks of N.W. Sutherland, it had been recognized that the key to the structure of the Scottish Highlands was to be searched for in that region. Accordingly, in the years 1883 and 1884, Mr. Peach and Mr. Horne were entrusted with a careful study of the Durness and Eriboll districts. They were very far from being directed to obtain means of justifying the old survey. "It was a special injunction to the officers" (we quote Geikie's own words) "to divest themselves of any prepossession in favour of published views, and to map the actual facts in entire disregard of theory."

From the work ably carried on by the distinguished surveyors, and verified on the spot by the Director-General, it appeared clearly that Murchison had been deceived by prodigious terrestrial disturbances, of which, at the time, nobody could have formed an idea. Over immense reversed faults, termed *thrust planes* by Geikie and his officers, the older rocks on the upthrow side had been, as it were, pushed horizontally forward, covering much younger sediments, and the displacement attained the almost incredible distance of more than ten miles. Sometimes an outlier of the displaced ground was found capping a hill, while the remainder had been swept away by erosion, and the strangeness of the case led the observer to write, "One almost refuses to believe that the little outlier at the summit does not lie normally on the rocks below it, but on a nearly horizontal fault."

Disturbances of that kind had already been noticed in some coal-basins, as, for example, on the southern limit of the French and Belgian coal-field, where similar outliers had been termed by M. Gosselet "*lambeaux de*

poussée" But they occurred on a much smaller scale, and there was no reason why the phenomena should be considered otherwise than as quite exceptional To recognize the generality of that class of stratigraphical accidents was a conquest of a high order, not only for Scottish geology, but for all countries where the work of orogenic disturbances has for a long time suffered from the agencies of erosion The Highlands of Scotland belong to that part of the old European continent which in earlier Palæozoic times emerged from the sea Near the end of the Silurian period it was subjected to enormous pressure, which resulted in folding and breaking the whole border of the dry land, raising in the air a series of high mountainous ridges, the Caledonian chain of M. Suess. But millions of years have since passed over the land, and the continued action of atmospheric powers has left but a very small part of the original mass It is extremely difficult, therefore, to restore the broken continuity, and through the quiet appearance of the now planed ground, the geologist is everywhere bound to search after the scattered signs of previous plication and fracture This is now the task to be fulfilled by the detailed Survey, and every stratigraphical difficulty has to be treated in the newly-acquired light

A few years after that discovery had been made in Scotland, Prof Marcel Bertrand made in Southern France quite similar observations, showing that very limited patches of older formations, which had been till then regarded as remnants of ancient islets, projecting out of younger geological seas, were nothing else than outliers of reversed folds, the remainder of which had disappeared under the action of rain and rivers

In this manner the correction of a long accepted error has led to stratigraphical conclusions of the highest import In the meantime these gigantic displacements showed themselves accompanied by intense modifications of the rocks, so that Geikie was entitled to write "In exchange for this abandoned belief, we are presented with startling new evidence of regional metamorphism on a colossal scale, and are admitted some way into the secret of the processes whereby it has been produced"

This is not the only occasion on which Sir Archibald has given proof of his readiness to admit frankly and decidedly the correction of opinions which have long been held Some years ago, when the Lower Cambrian fauna had been detected by the officers of the Survey much below the Durness limestone of the Highlands, in a series of strata which rests unconformably on the Torridon sandstone, he was the first to announce the fact before the Geological Society. The "Precambrian," which he had till then been rather reluctant to recognize, has now taken its place in the scale of divisions Moreover, he has created a new name, that of "Dalradian," for the long strip of Precambrian deposits which extends from Donegal to the centre and south-west of Scotland.

As one of the most characteristic formations in Scotland is the Old Red Sandstone, we cannot be surprised that Sir Archibald has devoted much care to the description of the peculiarities of that interesting group of strata. After a long and detailed study of the whole ground, he has summed up his views in some important memoirs, published in the Transactions of the Royal Society of Edinburgh. There he has called again to life the

old and long-extinct lakes, where the grits and conglomerates of the Old Red were piled up through the disintegration of surrounding formations, namely, Lake Orcadie, Lake Caledonia, Lake Cheviot, Welsh Lake, and Lake of Lorne, each of them being a separate basin, where the work of sedimentation has been many times interrupted by volcanic outbursts, while in the adjacent and more quiet seas there were accumulated the marine deposits of Devonshire

But the chief work of Sir Archibald seems to be his exhaustive review of the volcanic history of the British Isles. While his brother, Dr James Geikie, the author of "The Great Ice Age," has done excellent service by deciphering the marks of former ice action on the soil of the United Kingdom, Sir Archibald has been particularly attracted by the work of fire, & by the records of that volcanic activity, the evidence of which is so deeply impressed on the scenery of the Hebrides, of Wales, and other districts of Great Britain

The British Isles are now a very quiet ground, where explosive activity and projection of stones seem to be restricted to electoral periods, and although Scotland has been from time to time shaken by minor earthquakes, no human eye has ever seen there any volcanic outburst. Nevertheless, during Tertiary times, immense sheets of lava were poured out in the north-west of the country. To discern the site of the centres of eruption, and determine the old chimneys, the remnants of which give a glimpse into the lowest parts of ascending lavas; to discriminate the volcanic *necks*, the intrusive sheets and dykes, the bedded lavas and the tuffs—this was the first part of the task undertaken by Sir Archibald But it was not enough for him to re-ascend in the past to the beginning of the Tertiary period Not only in the Old Red of Scotland, but in the very heart of the oldest formations known in England and Wales, there were numerous evidences of previous volcanic activity To use Geikie's words "Placed on the edge of a continent and the margin of a great ocean-basin, the site of Britain has lain along that critical border-zone where volcanic energy is more active and continuous"

The chief outlines of that marvellous story, which was hardly suspected some years ago, were recently traced in Geikie's presidential addresses to the Geological Society of London, a work which has been qualified by Mr Iddings, the distinguished American petrographer, as "one of the most important contributions to the history of volcanic action." Nevertheless, it is only a preliminary paper, and in the same manner as he already has devoted a special memoir to the volcanic outbursts of Tertiary times, Sir Archibald promises to publish in a short time a detailed account of the Palæozoic eruptions.

In order to become competent for such an undertaking, the author had prepared himself without sparing time, labour, or trouble Having travelled over much of Europe, from the north of Norway to the Lipari Islands, he was anxious to learn from personal observation the broad features of that American continent, the geological construction of which seems to have been conceived on a much larger scale than that of Europe Therefore in 1878 he rambled over many hundreds of miles in Western America, from the Archæan fields of Canada to the huge volcanic plateaux of Oregon and

Idaho, where a country as large as France and Great Britain combined has been flooded with a continuous sheet of basalt. But stratigraphical studies were only part of the necessary initiation. Sir Archibald had been one of the first field-geologists in England to perceive the importance of microscopic investigation as an adjunct to field work. He might well have left the care of that special study to some officer in the Survey, but he wished to make himself master of the subject. Connected by personal friendship with Zirkel, Renard, and other eminent petrographers, he gave to that branch of the Survey such a vigorous impulse, that upwards of 5000 slices of British rocks were soon prepared and classed in the collections of the museum in Jermyn Street, and if he can now rely with full confidence on his distinguished professional officer, Mr. Harris Teall, for any determination of rocks, he himself has won all necessary competence in that department of science, which has been so much enlarged during the last twenty years.

An undertaking so ably provided for could not but prove successful. It is not, of course, our purpose to give an account of the results arrived at. The "History of Volcanic Action in the Area of the British Isles," as it was presented in the presidential addresses for the years 1891 and 1892, is so much condensed that it must be read *in extenso* by every one who takes interest in the matter. We would only call attention to the final summary, where some important and far-reaching conclusions are deduced from the observed facts. One of them is that British volcanoes have been active in sinking rather than in rising areas, to which it is added that the earlier eruptions of each period were generally more basic, while the later intrusions were more acid.

When presenting "a connected narrative of ascertained knowledge regarding the successive epochs of volcanic energy in this country," Sir Archibald did more than write an important chapter of British geology. It may be said that he definitively settled the long-controverted question, whether there has been any essential difference or not between the display of volcanic activity at various geological periods. Not very long ago some scientific schools—above all, on the Continent—showed the greatest reluctance to admit that true volcanoes could have existed during the Palæozoic era. When they were told of Cambrian lavas and felspathic ashes, of Silurian tuffs, especially of Precambrian felsites, they could not restrain a strong feeling of incredulity. Against old granitic or porphyritic eruptions they had nothing to object; but the volcanic *facies* appeared to them a privilege restricted to recent geological times. To this the present writer might bear personal testimony, as he found his "way of Damas" only when he was fortunate enough to ramble over North Wales, and gather with his own hands pieces of vesicular lava embedded in the tuffs of the Snowdon, or boulders of true felsite lying at the base of the Cambrian series at Llanberis.

Not only has Sir Archibald, in common with his countrymen, always escaped that kind of misconception, but he will have contributed more effectively than any other to place the matter in the true light. Thanks to the cliffs of Scotland, he has been able to trace the roots of old volcanoes, to show true volcanic bombs entombed in

sediments, and to mark the site round which vast piles of lavas and tuffs, 5000 or 6000 feet in thickness, had been heaped up. Likewise, in his previous paper on Tertiary volcanoes, he had established by indisputable sketches that the granitic rocks of the islands of Mull and Skye were ejected during the earlier part of the Tertiary period, and that they belong to the central mass of intrusions, the lateral veins of which have taken the form of granophyres.

There is another kind of useful geological work which Sir Archibald has a right to be credited with, we allude to the restoration of the most friendly relations between the official Survey and the Geological Society of London. For many years those relations had been maintained at a rather low temperature, both independent geologists and Government's surveyors showed, as it were, more inclination to mutual and severe criticism than to brotherly co-operation. This period of misunderstanding is now well over. Thanks to the present Director, the Geological Society has more than once received the early flower of the capital results obtained by the Survey, and the recent Presidentship of Sir Archibald has solemnly sanctioned the return of a harmony which will prove of great benefit to the advancement of geological science in England.

This is a very brief and imperfect account of the chief work accomplished by the field-geologist, a work which would have been sufficient for the whole of a man's life. But we have now to consider in Sir Archibald the master who has been engaged in important educational duties. When he was appointed in 1871 to the chair of Geology at Edinburgh he had the whole work of that department to organize, a task which may be wearisome, but which involves great benefit for a man of labour, as he must face every difficulty, and obtain day by day a clear and personal idea of all that is required for teaching. To that we are indebted for the undisputed superiority which Sir Archibald has displayed in his "Text-book," as well as in his other educational writings, such as the "Class-Book," a very model of clearness, whereby it has been once more demonstrated that those only are qualified for writing elementary books, who are in the fullest possession of the whole matter. Likewise he is the author of small books or "primers" on physical geology and geography, of which some hundreds of thousands of copies have been sold, and which have been translated into most European languages as well as into some Asiatic tongues. This exceptional success will be easily understood if we remember that in Sir Archibald's works the traditional barrenness of geology is always smoothed and adorned by a deep and intense feeling for nature. Nobody has done more than he to associate geological science with the appreciation of scenery. In numberless writings he has undertaken to explain the origin of existing topographical features. Among others reference may be made to the volume on "The Scenery of Scotland viewed in connection with its Physical Geology," first published in 1869, of which a new edition appeared in 1887, also to "Geographical Evolution," in the Proceedings of the Royal Geographical Society for 1879, and "On the Origin of the Scenery of the British Isles," published in NATURE (vol. xxix. pp. 347, 396, 419, 442).

Nevertheless, whatever might have been the attainments of the geologist and of the teacher, they would not have been sufficient to secure universal recognition, had not Sir Archibald been provided in addition with the best powers as a writer. From the beginning he was strongly convinced of the importance of cultivating the literary element in scientific exposition, not only in order to make science interesting and intelligible to those outside the circle of actual workers, as he did in writing "Geological Sketches at Home and Abroad," but because he did not admit the right of a man of science to appear before the public without putting on the "nuptial dress." Every one who knows Sir Archibald will readily admit that in doing so he is not impelled by a desire for personal display. He is essentially a man of thought as well as of action. "*Res non verba*" might well serve him as motto, and whoever has seen his silent but piercing attention in listening to some scientific controversy would never be tempted to suspect him of a wish to search after re-sounding manifestations. But he has too much of the artist's temper to neglect correctness and elegance in the utterance of his thoughts. And since nothing in the world is less common than the union of scientific insight and acuteness with a vivid appreciation of nature and a delicate feeling for style, it is not strange that Sir Archibald's fame has passed far beyond the circle of professional men. The portrait will be duly completed when it is added that no one could have a better renown for frankness, fair dealing, and perfect trustworthiness in every relation of life.

It is highly gratifying for England that the recognition of such achievements has not been left to future times, and that the present generation has not failed in the duty of rewarding so much continuous and fruitful labour. He was admitted to the Royal Society before reaching the age of thirty, a most unusual honour; he has been Vice-President, and was recently elected Foreign Secretary, of that Society. Since 1890 an Associate of the Berlin Academy, elected by the Royal Society of Sciences at Göttingen, after the death of Studer, the Nestor of Swiss geologists, enrolled among the members of the Imperial Leopold-Caroline German Academy, of the Imperial Society of Naturalists of Moscow, &c., &c., he was chosen in 1891 as a correspondent by the French Academy of Sciences, and in the same year he was made a knight. An honorary LL.D. of the Universities of St. Andrews and Edinburgh, he has received the Murchison medal of the Geological Society of London, and twice the MacDougal Brisbane Gold Medal of the Royal Society of Edinburgh has been conferred on him, in recognition of the zeal and skill displayed in explaining the geological peculiarities of his mother-land. He is now at the summit of his career, and not so heavily laden with years but that we may express for him the wish *ad multos annos*. Let us hope that he will long remain at the head of the distinguished staff to which he has given so profitable an impulse, and continue to serve as a comforting example for those who refuse to acknowledge any other means of genuine success than constant labour and faithfulness to duty.

A. DE LAPPARENT

# SHAKING THE FOUNDATIONS OF SCIENCE<sup>1</sup>

TO judge by the columns of the daily press, we must expect to find a large number of enterprising company-promoters coming forward shortly to urge, in Parliament and elsewhere, that leave may be given them to confer lasting benefits upon Londoners. The good they propose to do comes in the shape of underground intercommunication. Locomotives of the ordinary construction, it would seem, are not to be employed, but instead of them cable traction or electric energy in some shape or another. On these points, however, we must speak with caution, for we are told that an absence of definite statements and programmes is one of the main features of the pronouncements so far issued.

On two previous occasions it has been our duty to draw attention to a scheme, intended to provide more ready means of intercommunication between different parts of London, which threatens to inflict serious damage upon the property of the nation.

It so happens that one of the schemes to which reference was made in the opening paragraph is a rehabilitation and expansion of that very project against which we protested on the previous occasion. The attempt, which has already once been thwarted, to render the study of the sciences involving exact measurement impossible at South Kensington, is again to be repeated, and it is necessary to warn the public that an enterprise undertaken nominally for their interests, which are, or the moment, regarded as identical with those of the company promoter, will strike a fatal blow at the utility of institutions on which many thousands of pounds of money, public and other, have already been spent, and on which it is in contemplation to spend many thousands more. Our protest on the former occasion was based on scientific grounds. There were others strongly urged from other points of view, and as a result of the opposition the scheme was withdrawn for a time.

In the shape it now assumes it is still more objectionable, as the scope is now a more ambitious one.

Our objection was simply to the route to be followed. In London we have only one locality where telescopes are nightly used by teachers and students; we have only one institution the function of which is limited to physical and chemical teaching and research, where delicate measurements are essential, and form part of the routine work; we have only one institution, the function of which is to teach applied science in the most efficient manner—that is, by teaching in which experiment and observation, and of extreme delicacy, must go hand in hand with the  *viva voce*  exposition of the professor of each branch of applied science.

The contemplated railway proposes to sweep all these away. Astronomical Observatories, the various Laboratories of the Royal College of Science, and of the City and Guilds Institute, are not to be considered the least in the world. This is practically what it comes to, for we doubt whether either teacher or taught will care to remain in a locality where neither valid experiments nor observations are possible.

<sup>1</sup> Continued from vol. XLII. p. 148.

We need not waste time in considering whether some means could not be found to continue to take astronomical photographs of say an hour's exposure, or to use chemical balances of the greatest delicacy, with a railway or tramway of any kind running intermittently within twenty yards of the laboratory in which the work is supposed to be carried on, and it is also clear that the result would be disastrous if the traffic were carried on at any practicable depth.

Last year a joint Committee of the Houses of Lords and Commons fully considered the question as to the principles on which future extensions of what may be called omnibus traffic should be carried on, and they came to the conclusion that electric and cable railways constructed at a considerable depth below the surface would probably be the most convenient means for uniting the various parts of the metropolis more closely.

Some people have attempted to read into this part of the Committee's report that given a cable or electric railway *there will be no shaking!* And it has been suggested that all such opposition as we have expressed above should disappear. This of course is the view of the company-promoter, but it will commend itself to no one else. In fact there are special objections to an electric railway in addition to those earthquakes more or less mitigated which are associated with any system of traction.

No evidence was laid before the Committee as to some of the disadvantages which are incidental to the use of electricity. It is true that these disadvantages are not such as to interfere with the further extension of electrical railways, but they are of sufficient importance to be considered in deciding on the routes which the railways shall follow. Experiments made some little time ago in the neighbourhood of the South London Electrical Railway proved that the electrical disturbances were so great that it was doubtful whether ordinary higher students' work could be carried on within a quarter of a mile.

A quarter of a mile! And the proposed railway, or electric way, or cable way, or tramway is to run within twenty yards of electrical and magnetic laboratories. "*Rien n'est sacré pour un sapeur!*" an evil hidden in the ground ceases to be one.

It must not be forgotten that the interests at stake are not only those of the higher sciences and research. It might, perhaps, be argued that as the instruments used for investigation become more sensitive, and as the necessity for accuracy increases, it may be necessary that researches of a special character should be carried out in places specially selected for their freedom from all external disturbance. A serious damage will, however, be done to our large towns if it becomes necessary for every middle-class youth who wants to master more than the elements of science to become a boarder at a country college. It is frequently complained that there is an increasing separation between class and class, those who are able to do so leaving the towns for the more distant suburbs. It would be a thousand pities if the higher education were also, even in part, to be banished from our great centres of population.

It may be urged by the promoters of the company that it will be easy for them or the Government to plant the

Royal College of Science elsewhere, but if the buildings of the College are notoriously inadequate, it was clearly stated at the time when the proposal to place a collection of pictures on the site reserved for science made it necessary to explain the future policy of the Department of Science and Art, that the collections and the laboratories attached to them were in the future to be housed on the plot close to the present site.

But as stated before, it is not necessary only to base our case upon the injury which would certainly be done to the Royal College of Science, it must be remembered that hard by is the City and Guilds Central Institution, in which extensive and costly laboratories, built by the munificence of the City Companies, have during the last few years been filled with students, many of whom are engaged in advanced studies.

A very argument which applies to the one case holds good in the other. The work of the City Companies and the interests of these institutions are endangered in the same way, and for the same reasons, as those of the Government College over the way.

On the previous occasion, when it was proposed to bring a railway at the back of the Central Institution, the Professors there, with the sanction of the City and Guilds of London Institute, opposed the scheme. We understand that the Professors have again made a representation to the Institute which in all probability will result in steps being taken to prevent the construction of any railway or tramway which would interfere with the work carried out in the Physical Department of the Central Institution.

In both these institutions it is as important that the apparatus should be used without let or hindrance from external disturbances, as say, that the reading-room in the British Museum should not be rendered uninhabitable by a nuisance produced either by private individuals or by some company in the neighbourhood.

On these grounds we protest in the name of science against a railway of any kind in Exhibition Road.

If there is one district in the metropolis which ought to be thus secured, it is the neighbourhood of the great national scientific school and its associated collections.

And here a word about these Science Collections. There are philistines among us who think that the collections would do very well without the schools, as the schools could do very well without either higher teaching or research.

There is no doubt a certain advantage to be gained by collecting types of all sorts of apparatus, exhibiting them appropriately labelled in glass cases, through which the public may gaze with, it is to be feared, somewhat indiscriminate admiration, but it must always be recollected that the nation is proud of the British Museum and Art Galleries, not merely because they play a useful part in educating the crowds who visit them, but also because they are centres to which students resort from all parts, not only of the United Kingdom, but of the civilized world, not to gaze at the collections but to use them. In like manner a national collection of scientific apparatus should be brought together, not merely to be stared at, but to be used. By an arrangement more logical than those to which our haphazard English

customs too frequently lead, this second object is at present attained

It is almost ludicrous that at the very moment when a Royal Commission is sitting to determine the constitution of a new University for London, Parliament should be asked to sanction a Bill which, if it serves as a precedent, may make the teaching of some of the most important sciences impossible within the metropolitan area. Indeed, in this danger we find a new confirmation of the importance of the policy which we have often urged upon those who are directly interested in the constitution of the future University.

Science teaching in Exhibition Road is threatened to-day. It may be threatened somewhere else to-morrow. It will be impossible for a number of competing colleges to defeat the railway engineers, or to preserve intact for scientific research a number of buildings planted upon sites selected without reference to the new danger which has arisen. They will be attacked in detail, and beaten one by one. How immensely in this, as in many other matters, would their position be strengthened if they were able to speak with one voice in support of a plan decided on in common, and defended together. If the hoped-for University of the future already existed, if it spoke with the prestige of the existing University of London, combined with that of the consolidated teaching staffs of the London Colleges, if the support of a Government Department could be asked to aid a University which, like the British Museum, commanded universal respect and support, then it might be possible to obtain a ready hearing for opinions given with all the weight of a great institution of which the country would be justly proud. Till the union is effected, which alone will make science in London able to meet its enemies in the gate, we must struggle as best we can to prevent irreparable mischief.

We can only hope that the Vice-President of the Council, who is known to have the interests of the higher education at heart, will not allow a railway, electrical or other, to injure the teaching institutions clustered round the magnificent collections of apparatus in his charge.

### SOUND AND MUSIC

*Sound and Music.* By the Rev J. A. Zahm, C.S.C., Professor of Physics in the University of Notre Dame. Large octavo, 452 pages (Chicago: A.C. McClurg and Company, 1892).

**T**HIS handsomely got-up and lavishly illustrated volume is, the author informs us, a largely expanded transcript of a course of lectures delivered by him, in 1891 "in the Catholic University of America, at Washington, D.C." Its "main purpose is to give musicians and general readers an exact knowledge, based on experiment, of the principles of acoustics, and to present at the same time a brief exposition of the physical basis of musical harmony." A clear intimation is given at the outset (p. 18) of the predominant rôle which experiment is to play in the acoustical portion of the undertaking. Had Prof. Zahm not had at his disposal "all the more delicate and important instruments" of research and verification, in the

theory of sound, constructed by Dr. Koenig of Paris, he would "not have attempted to give the present lectures on sound" before such an audience as that which actually attended them. With Dr. Koenig's apparatus around him, however, he had assured means of "entertaining" his hearers, and of "illustrating in a way that would otherwise be impossible the most salient facts and phenomena of sound." The late Isaac Todhunter has deprecated the systematic repetition of perfectly established experiments, on the ground that their results ought to be believed on the statements of a tutor—"probably a clergyman of mature knowledge, recognised ability, and blameless character"—to suspect whom was in itself irrational! Prof. Zahm's practice pushes to a great length a view directly opposed to that enunciated—with obvious humorous exaggeration—by the well known Cambridge private tutor. Not content with a single experiment decisive of each successive issue presented, he performs a whole series bringing into action all the resources of his superbly found collection of acoustical apparatus. It is no detraction from the clear and interesting manner in which these formidably numerous experiments are set forth, to say that the amount of space necessarily devoted to explaining the mechanism of the apparatus used gives to parts of Prof. Zahm's volume somewhat of the look of an acoustical instrument-maker's illustrated catalogue. Subject, however, to this defect, if defect it be, the lectures are decidedly pleasant and attractive reading. The illustrations, too, are thoroughly clear and beautifully executed, so that our author may be fairly congratulated on success in 'entertaining'—the word is his own—his hearers and readers. His object, to give to general readers an "exact knowledge" of the principles of acoustics, has also been in a fair measure attained, but subject to certain not inconsiderable deductions. In describing the processes and results of experiment Prof. Zahm is clear and thoroughgoing in expounding the parts of acoustical theory which must be mastered if the facts thus obtained are to be understood in their mutual relations, he is often vague and superficial. Thus the nature of wave motion, the formation of stationary undulations, the composition of small vibratory movements—matters of crucial importance to any connected comprehension of Acoustics—receive from him no effective elucidation. Nay, he is even chargeable with having, by the misuse of a technical term of perfectly settled meaning, written in a way likely to confuse his readers' ideas on these very matters. On p. 46 he calls certain points in a series of progressive waves "NODAL points where there is no motion," thus confusing two things which ought to be most carefully distinguished from each other, a point of *momentary* rest in a *progressive wave*, and one of *permanent* rest in a *stationary undulation*. The usage which restricts 'node' to this latter meaning is so well established that such use of it as the above is quite inexcusable, especially in an author who himself elsewhere, p. 146 &c., employs it in its ordinary signification. The same indifference to accuracy of expression recurs in this volume with a frequency not creditable to a professor of an exact science. Thus on p. 50 the return movement of a prong of a tuning fork is said

<sup>1</sup> "The Conflict of Studies," p. 17.

to 'pull' air particles apart. On p 52 we are told that the motions of particles of a water wave "are always at right angles to the direction of the wave itself" On p 68 the author corrects this statement, but in doing so, takes occasion to speak of a plane "in," instead of 'passing through' the line of progression On p 380 he describes harmonic partial-tones as "modifying the quality of their fundamental," though he obviously means the quality of the compound sound due to the fundamental and other partial-tones combined On p 387 it is said that the "ratios of frequencies" which characterize particular sounds "are called intervals," and that by dividing one note by another we obtain the intervals between them Language of this kind is, indeed, hardly misleading, but it is certainly very slipshod.

Before passing from the more generally acoustical, to the more specially musical portion of Prof Zahm's volume, it is proper to point out one important respect in which it has the advantage over most, or possibly all, the manuals on the same subject which have preceded it This merit consists in giving a somewhat full account of elaborate experimental researches on beats, combination-tones and quality conducted by Dr Koenig, the results of which are to a considerable extent at variance with conclusions previously announced by Prof. Helmholtz. In the opinion of our author, Dr Koenig is "one who, not excepting even the eminent German philosopher just mentioned (Helmholtz), has contributed more than any other person to the advancement of the science of acoustics" (p 17) A more balanced judgment, while placing great reliance on Dr Koenig's experimental skill and on the superlative excellence of the apparatus constructed by him, would probably attribute to Helmholtz's opinion a preponderant weight in interpreting and correlating the results of experiment Be that, however, as it may, Prof Zahm has done excellent service by popularizing the work so laboriously performed, and so modestly placed on record, by the eminent instrument-maker to whom no one who has put his hand to acoustical work can fail to be under considerable practical obligations

The specifically musical are decidedly the least meritorious parts of our author's performance The looseness of phraseology already complained of is here at its worst On p 166 we are told that a 'comma,' ( $\sharp\flat$ ) is "the smallest interval used in music" A beginner might easily take this to mean that notes differing by only that interval were actually heard consecutively in a musical phrase—of course an absurd supposition Very misleading, again, is the statement on p 388 that tones, like major and minor tones, that differ from each other only by a comma "are considered in music to have the same value" The only rational meaning to be got out of it seems to be that in the *equally tempered scale* the distinction between major and minor tones is obliterated On p 389 the notes of the diatonic scale, and their relations, in respect to rapidity of vibration "to one another," are set out, and it is added that all but the second and the seventh of the intervals thus indicated are consonant The essential piece of information, that it is not the intervals formed by these notes with "one another," but with the *tonic*, that are in question, is with-

held, and so the reader is left free to suppose *eg* that the tritone, F--B, is a consonance On p 390 the 'inversion' of intervals is mentioned without any explanation of its meaning

Attention may well be called to a process of reasoning which occurs on pp 388 390 Prof Zahm abruptly introduces (p 388) calculation by "frequency ratios", assumes, without attempt at proof, that addition of two semitones is performed by squaring the ratio  $\frac{1}{2}$ , and then remarks (p 390) "From the foregoing we observe that the sum of two intervals is obtained by multiplying, not by adding their ratios together" An *assumption* in a *particular case* is thus made to do duty as a *general demonstration*

On p 396 we read that "so perfectly does the interval of the fifth answer the requirements of the ear that even unpractised singers find it quite natural to take a fifth to a chorus that does not quite suit the pitch of their voice" If, as this passage appears to suggest, practised singers in America find it still more natural to accompany melodies in consecutive fifths, wonderful effects may surely be expected from the choruses to be heard at the Chicago exhibition

On p 429 our author describes a diagram by Helmholtz as concerned with the transposition of an interval by an octave, whereas what it really deals with is the enlargement of the interval in question by the addition to it of an octave On p 430 he writes down, *as constituents of the chromatic scale of C*, the notes E $\sharp$ , F $\flat$ , B $\sharp$  and C $\flat$

On p 441, he tells us that in listening to such violin players as Joachim, Wilhelmj, and others "one can always hear distinctly the *Tartini*, or beat-tones, that add such richness and volume to violin music"

To gauge the amount of truth contained in this remark it suffices to bear in mind that in the case of most major, and of all minor consonant chords, Tartini's tones cause a *decided dissonance* Players who made them 'always distinctly audible' would soon be reduced to permanent inaudibility themselves

Prof Zahm's volume is creditably free from misprints the following have, however, been noted

- P 23, l 16 'period' for 'periods'
- P 68, l 21 'amplitude' for 'amplitudes'
- P 90, l 8 'Ajugari' for 'Agujari'
- P 142, in diagram, B $\sharp$  for B $\flat$
- P 152, in diagram I, B $\sharp$  for B
- P 388, ll 11 and 12, G for F

#### GERLAND'S ETHNOLOGICAL ATLAS

*Atlas der Völkerkunde.* (Berghaus' Physikalischer Atlas, Abth VII). Bearbeitet von Dr Georg Gerland, Professor a d Universität in Strassburg (Gotha, Perthes, 1892)

ANTHROPOLOGY owes much to Prof Gerland, whose completion of the two last volumes of the late Prof Waitz's "Anthropologie der Naturvölker" is a monument of that co-ordinated knowledge of fact which is the source of sound principle His new "Atlas of Ethnology," while forming part of the great Physical Atlas of Berghaus, may be obtained and used as a separate work by anthro-

pologists, to whom it will be of great service in methodizing the vast and growing information with which they have to deal. This application of graphical method, it is true, has difficulties which even the greatest skill cannot altogether overcome, but Prof Gerland may well be content with his success in making evident at a glance the characteristics of mankind, seen from many points of view. Their distribution over the earth, as thus made evident, may often lead straight on into theories of origin. The fifteen plates contain nearly fifty maps, each suggesting a principle, or showing where there is room for one.

Plate I. represents on two planiglobes the classification of human races as to skin and hair. Prof Gerland does not even combine these two characteristics, and points out in his introductory remarks that any attempt to map out man into defined physical races is impossible, for such division does not exist in nature. Anthropologists of course know this, but care is not always taken to make it clear that race-types are not so much complete realities as statistical abstractions from partial realities, the various measurable characters of skull, limbs, complexion, hair-form, &c., combining and blending too intricately for absolute definition. I was struck by meeting lately in a popular book with a confident mention of the four distinct Aryan race-types, and it occurred to me that it would bring the statement down to its bearings to put one of Prof Gerland's planiglobes before the author, desiring him to define and map out these varieties of mankind. Even in Gerland's broad general distinctions of complexion and hair, an anthropologist not thoroughly special on the anatomical side may find novelty and difficulty. The opinion that all native Americans are similar as to race is here strongly and probably with reason modified by the native Brazilians being separated on the complexion-map from other peoples of North and South America, and placed to match the Tartars and Chinese. What amount of evidence there is for placing the Berbers of North Africa under the same map-colour seems not so clear, but it is to be noticed that the same tint includes several more or less distinct grades in Broca's scale. An attempt is even made to separate the friz-haired negroids into classes according to the arrangement of their corkscrew-tufts of hair on the skin. Plate III., in two maps, classifies man according to his religious beliefs and customs, and here the prevalence of special rites offers instructive generalizations. Thus the American line which limits the smoking of tobacco as a religious ceremony, indicates the spread of this peculiar rite from some religious centre over an enormous area. No doubt it is rooted in nature, from the fact that its narcotic ecstasy brought the priest into direct visionary contact with the spirit-world. But none the less, it proves the religions of savage tribes, separated by great distances on the map, to be bound together by historical connexion. Not less remarkable is the compactness of the districts of Eastern Asia and the opposite Continent of America, where masks are used, apparently originally with religious significance. Here again it is evident that we have to do not merely with independent growth from the human mind, but in some way with historical transmission. It must be remembered in using these maps, that they bind their author only to fact, and not to theoretical interpreta-

tion. This same plate maps out the immense districts whose natives have a myth of a deluge, the upheaving of the earth, &c., but it cannot distinguish in North and South America, for instance, between regions where deluge-myths are old, and those where they were introduced by the Jesuits a few generations ago. Plate IV., mapping out regions liable to special diseases, as malarious fevers, pestilence, cholera, yaws, &c., contains in a condensed form a vast collection of knowledge, bearing on anthropological arguments as to the relation of race to physical constitution, and thus opening into one of the great problems of the history of man. Plate V. classes out the varieties of human food, clothing, dwellings and occupations. Plate VI. and onward map out the distribution of nations and tribes at different periods as known to history, Plate XIV. being devoted to the distribution of languages over the world.

Anthropologists who keep this atlas at hand as a help in their work will by practice find out its merits and defects. The representation of the geographical distribution of arts and customs has long been a feature of the Pitt-Rivers Museum, where so far as possible each series, illustrating development and transmission of culture, is accompanied by a small world map coloured to show the parts of the world it occupies. It is of course impossible to Prof Gerland to work in such detail, involving as it would do hundreds of separate charts. He has to indicate his distributions on a moderate number of plates and mostly uses planiglobes, a projection which, after being neglected for generations, will, in its improved modern arrangement, certainly come into more general favour. On these, by ingenious devices of tinted patches and streaks, combined with lines and dots, he succeeds in giving a more general survey of man and civilization than our students have ever had in their hands before.

EDWARD B. TYLOR

#### OUR BOOK SHELF

*Castorologia, or, The History and Traditions of the Canadian Beaver.* By Horace Martin, F.Z.S. (London: Stanford, 1892.)

"BEAVER" was once the most important fur in the world. In former days the pelt of this Rodent was the standard by which all barter in the Dominion of Canada was regulated, and "beaver" passed as current coin throughout the whole of North America. Even now the quantity of beaver skins brought to England is considerable. Mr Poland, in his "Fur bearing Animals," tells us that upwards of 63,000 beaver skins were sold by the Hudson's Bay Company in 1891. But "beaver hats" formerly required a much larger supply than this, and in 1743 it is said that 127,000 beaver-skins were imported into La Rochelle alone. Our "top" hats are now made of silk, and beaver has become a fur of second-rate importance.

Besides the fur of the beaver many other points of interest attached to this animal will be found discussed more or less completely in Mr Martin's volume. Long before its fur was required for hats *castoreum* or *castoreo*—a substance found in two large glands, situated near the base of the beaver's tail—was a much-valued specific in medicine, as spoken of by Hippocrates and Pliny. Even at the present time its use is by no means abandoned, and the "crude article" is "still sold at our drug-stores" at prices varying "from eight to ten dollars a

pound." But in past centuries castoreum was considered a sovereign remedy for every kind of disease. Many amusing details on this part of the subject are given by Mr. Martin, mostly extracted from the "Castorologia" of Johannes Francus, published in 1685. The wisdom of Solomon himself is attributed by this learned author to the virtues of the beaver. To acquire it, it is only necessary "to wear a hat of beaver's skin, to rub the head and spine with that animal's oil, and to take twice a year the weight of a gold crown piece of castoreum."

At the end of his volume Mr. Martin places a short account by Mr. C. V. Riley, the well known American entomologist, of *Platysyllus castoris*, a parasite on the beaver, and one of the most remarkable among the many extraordinary forms of parasitic insects. Mr. Riley correctly refers this creature to the coleoptera, although other naturalists, and, amongst others, its discoverer, Ritsema, have expressed different views on this point. He omits, however, to refer to the excellent account of *Platysyllus castoris*, written by the late John Leconte, and published in the Proceedings of the Zoological Society of London for 1872. Dr. Leconte has here shown that it is necessary to make a special family (*Platysyllidæ*) for the reception of this curious parasite, but that it must be unquestionably referred to the coleoptera.

On account of these and other peculiarities the beaver is unquestionably an animal of great general interest, and Mr. Martin has done well to devote a volume to what is evidently his favourite theme. There is, we must allow, little, if anything, original in it, and the statements on scientific points cannot always be implicitly depended upon. But the author has brought together a large amount of information on the subject, and his book is "popularly written" and "fully illustrated," though we cannot quite agree to his claims to have produced an "exhaustive monograph."

*An Atlas of Astronomy*. By Sir Robert Stawell Ball, LL.D., F.R.S. (London: George Philip and Son, 1892.)

A NEW book by Sir Robert Ball is always a matter of interest, but the present one naturally lacks the usual characteristics. It is described as "a series of 72 plates with introduction and index." In addition to monthly and general maps of the stars, the atlas reproduces pictures of the sun, moon, planets, and comets, and contains diagrams illustrating their motions and dimensions. As the book is chiefly meant to be a companion to more general works, the introductory matter is purposely brief, but still it has several features of interest. Special attention may be drawn to the excellent description of a simple graphical method of determining the orbit of a binary star.

To the serious student who may possess a small telescope the new atlas will be very useful. Here he may learn how to determine the positions of sun spots, how to find the places occupied by the various planets, and what objects are most likely to be within reach of his instrument. Those interested in selenography will derive much assistance from the twelve plates showing the moon at different phases, which have been specially drawn by Mr. Eger, each being accompanied by an index map. One can only wonder, however, that some of the recent excellent photographs of the moon have not been pressed into the service.

The star maps, on the whole, are excellent, and our only complaint is of the excessive density of the Milky Way, which, in some parts of the maps, is almost sufficient to obliterate the names and numbers of the stars. The monthly maps will be particularly useful to those who are just learning the constellations, a new feature being a belt indicating the track of the planets.

Spectroscopic astronomy is entirely omitted, the author being of opinion that this great branch of work can only

receive justice in a separate atlas. In this we heartily agree, and trust that such an atlas will soon be forthcoming.

The author's large following of readers will no doubt welcome the new comer, but we must express regret that astronomical photographs are not more fully represented. It would be interesting, for example, to reproduce a series of photographs of typical nebulae, all of which, we believe, are now available. A plate showing the advantages of photography in the delineation of stars would also add to the interest of the atlas.

## LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

### Vector Analysis

I FANCIED that, in reply to the voluminous letters of Prof. Willard Gibbs (*NATURE*, xliii, 511, xlv, 79), I had said in a few words all that is requisite (if, indeed anything *de* requisite) to show the necessary impotence, as well as the inevitable unwieldiness, of every system of (so-called) *Vector Analysis* which does not recognize as its most important feature the product (or the quotient) of two vectors —  $i.e.$  a Quaternion.

A recent perusal of the first four pages of a memoir by Mr. O. Heaviside (*Phil. Trans.* 1892) — for so far only could I go — has dispelled the illusion. For he calls the correspondence just spoken of a "rather one-sided discussion" — a truly Delphic delivery — cleared up, however, by what follows it. I particularly desired to read the memoir (which the Author had kindly sent me) as I hoped to learn from it something new in Electrodynamics. But, on the fifth page, I met the check-taker as it were — and found that I must pay before I could go further. I found that I should not only have to unlearn Quaternions (in whose disfavour much is said) but also to learn a new and most uncouth parody of notations long familiar to me, so I had to relinquish the attempt. In the last of the four pages of my progress, I had found that Mr. Heaviside (though, as above stated, he has a system of his own) is an admirer of Prof. Gibbs' system, to such an extent at least that he thinks "his treatment of the linear vector operator specially deserving of notice." There I was content to leave the matter.

But Mr. Heaviside has just published (*Electrician*, 9/12/92) an elaborate attack on Quaternions, of a kind which is calculated to do real injury to beginners. In answer to his remarks, in which he continues to point to me as the persistent advocate of a system which all right-minded physicists should avoid, I would simply refer him (and his readers, if there be such) to a brief Address which I gave a short time ago to the Physical Society of Edinburgh University (*Phil. Mag.* Jan. 1890). One or two sentences, alone, I will quote here:—

"If we can find a language which secures, to an unparalleled extent, compactness and elegance, and at the same time is transcendently expressive—bearing its full meaning on its face—it is surely foolish, at least, not to make habitual use of it."

"For (Hamilton) the most complex trains of formulæ, of the most artificial kind, had no secrets—he was one of the very few who could afford to dispense with simplifications: yet, when he had tried quaternions, he threw over all other methods in their favour, devoting almost exclusively to their development the last twenty years of an exceedingly active life."

The main object, however, of my present letter, is to call attention to a paper by Dr. Knott, recently read before the Royal Society of Edinburgh. Dr. Knott has actually had the courage to read the pamphlets of Gibbs and Heaviside, and, after an arduous journey through these trackless jungles, has emerged a more resolute supporter of Quaternions than when he entered. He has revealed the (from me at least) hitherto hidden mysteries of the Dyadic, and of Prof. Gibbs' strange symbols Put, Lap, Max, New, &c. The first turns out to be only the linear and vector function; and the others are merely more or less distressing symptoms characteristic of imperfect digestion or assimilation of  $\nabla$ . And when, at my request, Dr. Knott

translated into intelligible form the various terms of one of the less formidable formulæ of Mr Heaviside's memoir, I was surprized to find two old and very unpretending friends masquerading in one person like a pantomime Blunderbore. In one of his Avatars the monster contains, besides the enclosing brackets, no fewer than 24 letters, 12 suffixes, 3 points, and 5 signs. When he next appears he has still the brackets to hold him together, but although he has now only 18 letters, he makes up his full tale of 44 (or 46) symbols, for he has 9 suffixes, 3 indices, 3 points, 5 signs, and 3 pairs of parentheses. I used to know him as compounded of 14 separate marks only, viz. —  $V^2 \nabla \sigma + 2 S \nabla \nabla_1 S \sigma \sigma_1$ , but, unless I had required to dissect him, I should never have put him in anything resembling his new guise.

Dr Knot's paper is, throughout, interesting and instructive — it is a complete exposure of the retentions and defects of the (so-called) Vector Systems. "Wer diesen Schleier hebt soll Wahrheit schauen." I find it difficult to decide whether the impression its revelations have left on me is that of mere amused disappointment, or of mingled astonishment and pity.

P. G. TAIT

Edinburgh, 24/12/92

### Measurement of Distances of Binary Stars

WITH reference to Mr. C. E. Stromeyer's letter on the above subject, which appeared on p. 199, it may be of interest to point out that his plan of determining the distance of a binary star is by no means a new one.

The method was, I think, first suggested by Mr. Fox Talbot at the Edinburgh meeting of the British Association in 1871, but the mere idea was sufficiently obvious as soon as the possibility of determining velocities by the spectroscope had been demonstrated by Dr. Huggins.

The first discussion of the geometrical conditions of the problem was given by Prof. C. Niven in the *Monthly Notices*, vol. xxxiv. No. 7, where he exhibits the relation connecting the parallax, the relative velocity, and the elements of the orbit of a double star, and computes the value of the product ( $\pm V$ ) of the parallax and velocity for a small number of binary systems.

In a paper published in the Proceedings of the Royal Irish Academy for May, 1886, I examined the same question from a slightly different point of view, being at the time unaware of Prof. Niven's paper, and was led to similar results. An epitome of this paper was published in your *Astronomical Column*, vol. xxxiv. p. 206. From the results obtained it appeared that, all things considered,  $\gamma$  Coronæ Australis and  $\alpha$  Centauri were the most likely binaries to yield to this method of eliciting the secret of their parallax, while  $\alpha$ -Geminorum, one of the stars selected by Mr. Stromeyer, was shown to be most unfavourable on account of the situation of its orbit.

In the *Monthly Notices* for March, 1890, I again drew attention to the subject in view of the accuracy of the results obtained by the photographic method in the hands of Prof. Pickering and Prof. Vogel. In this paper I gave an extended list of binaries with the usual geometrical and dynamical elements, and in addition the two elements A and B on which the relative velocity depends. I also gave the greatest value which  $\pm V$  can attain in each case and the velocity to be expected in the case of those stars whose parallaxes had been determined.

Again in Mr. J. E. Gore's valuable catalogue of Binary Star Orbits, published in the Proceedings of the Royal Irish Academy for June, 1890, columns 18 and 19 are devoted to the constants A and B computed from my formulæ (which I may say ought more properly to be called Prof. Niven's formulæ on account of the priority of his paper) for eighty-one different orbits.

The subject has also been discussed by Miss Clerke in "The System of the Stars," pp. 199-201, where references to most of the original publications will be found.

I may perhaps add that the inverse problem of determining the elements of the orbit from spectroscopic observations alone has also been investigated by me in the *Monthly Notices*, vol. II. No. 5, where I have deduced the principal elements of the orbit of  $\beta$  Aurigæ, a spectroscopic double which no telescope can divide.

I have been disappointed that astronomers engaged on spectroscopic determinations of stellar velocities have not devoted more attention to observations of already known binaries, which

appear to me to offer a promising field of work, and have often regretted that at this observatory we have not the means of undertaking the investigation, and if Mr. Stromeyer's letter has no other effect than to bring the subject once more forward it will have done good service, but I should like to point out that the second of the stars selected by him ought on no account to be taken as a test of the feasibility of the method, since the accurate discussion of the conditions shows that unless this is an exceptionally remote system the velocity must be very small indeed. For instance, assuming Johnson's parallax, viz.  $0''.20$ , the relative velocity of the components amounted last year to only 0.6 miles per second.

In the northern hemisphere the most favourably situated binaries are  $\gamma$  Ophiuchi,  $\xi$  Ursæ Majoris, and, if Peters' orbit represents the real motion of the pair,  $\delta$  Cygni, while for the southern hemisphere special attention ought to be directed to  $\alpha$  Centauri and  $\gamma$  Coronæ Australis.

In Mr. Gore's Catalogue, referred to above, will be found all the materials for determining when to observe any known binary most favourably in this respect, and for deducing its parallax from the measures obtained, and it ought to be borne in mind before letting the subject sink back once more into oblivion, that, other things being equal, this method is most likely to succeed in the case of the most distant systems, where the parallax is so small that the ordinary trigonometrical method necessarily fails us, and that when the micrometer, the heliometer, and the stellar photograph break down, the spectroscope will sound the further depths with ever increasing facility.

Dunsink Observatory, co. Dublin. ARTHUR A. RAMBAULT

December 30

### December Meteors (Geminids)

THESE meteors were moderately abundant on the night of December 12, which appears to have been a very favourable one in regard to weather. The chief radiant point was observed in the normal position very close to  $\alpha$ -Geminorum, and there was a strong contemporary shower from a centre east of  $\beta$ -Geminorum.

At 10h. 10m. December 12, a fireball estimated to be twice as brilliant as Venus was observed by Mr. Booth at Leeds. It moved rather slowly from  $150^\circ + 43'$  to  $188^\circ + 41'$ , and divided into two pieces at the finish.

Mr. Wm. Burrows, of Small Lane, Ormskirk, writes to me with reference to a meteorite which he observed to fall at a later hour on the same night. He says the time was 6.52 a.m. (December 13), and refers to the phenomenon as follows:—"Seeing the meteor was coming to the earth I crossed the road to where it appeared to be falling, and it fell about two yards from me. When it struck the earth it made a noise like the report of a gun, it also went black instantly. While descending it had a tail of fire about a foot long. It is  $1\frac{1}{2}$  inch in diameter one way, and 1 inch another, and one inch thick."

Mr. Burrows sends drawings of the object, and it being still in his possession it is hoped the matter may be suitably investigated. Should it prove a veritable meteorite one interesting circumstance in connection with it will be that its descent took place concurrently with the shower of Geminids.

It is significant that December 9-13 constitutes a well-defined ærolitic epoch, rendered memorable by the fall at Wold Cottage, Thwing, Yorkshire, on December 13, 1795, and by many others, such as that at Massing, Bavaria, December 13, 1803, at Weston, Connecticut, U.S.A., December 14, 1807, at Wiborg, Finland, December 13, 1813, at Ausson, France, December 9, 1858, at Baudong, Java, December 10, 1871, &c.

Bristol, January 1

W. F. DENNING

### The Earth's Age

As Dr. Wallace (*NATURE*, p. 175) trusts "that on further consideration" I shall "admit that" my "objection is invalid," it is evident that I have failed to make clear to him my argument showing that his data do not warrant his conclusion.

He overlooks the fact that a thickness of 177,200 feet of sedimentary rocks is, standing alone, a perfectly indefinite quantity, to make it definite it must have a definite area.

As he mentions no area for it we are justified in assuming that he means the land area of the globe, whereas his calculation is made as though area were not of the essence of the problem, in short, as if the formation of a pile of sediment 177,200 feet thick, of no matter what area, were the problem.

In Sir A. Geikie's calculation and all other similar ones with which I am acquainted, the thickness of the sedimentary rocks is tacitly assumed to be their thickness all over the land area of the globe.

Dr Wallace's calculation leads to the absurd result that continents are growing nineteen times as fast as materials are produced to supply their growth.

Leaving the question of the conclusions to which Dr Wallace's data logically lead, I may say that I am not responsible, and do not hold him to be responsible, for the absurd theory as to the thickness of sedimentary rocks on which they are based.

In order to arrive at a scientifically accurate result, what we require to know is the present actual thickness in every part of the world, plus all the thickness which has previously existed in, but since been denuded away from, every area. The existing thickness in geologically explored areas can perhaps be ascertained within certain limits of error from geological maps and memoirs. For instance where the surface consists of Torridon Sandstone overlying Archean gneiss of igneous origin, the thickness of sedimentary rock is that of the Torridon Sandstone only, if we assume that the gneiss there is part of the metamorphosed original crust of the earth, for the existence of which Rosenbusch has recently argued.

It is easily demonstrable, first, that in many places the existing thickness of each formation, where undenuded, is far from being the maximum thickness, and, secondly, from the thinning out in some directions, or merging, near the old shoreline, into conglomerates, that some formations were never deposited over certain areas, indeed, the very existence of a sedimentary deposit necessarily implies that of land undergoing denudation and not receiving deposit, although it may well be doubted whether the land area was always nineteen times the area receiving deposit.

Reasoning from the deposits preserved as to those removed by denudation, it is highly improbable that any considerable area ever received either the complete series of deposits, or on the average anything like the maximum thickness of the deposits it actually received. In addition to this, some formations usually considered to be successive may be really contemporaneous, so that the figures representing maximum thicknesses usually taken in calculating the earth's age are probably far above the truth for the purpose in question.

The immense labour involved in calculating the existing thickness of sedimentary rocks in each area, and the thickness which there is any reasonable ground for supposing to have been at any time denuded from that area, as well as the uncertainty of the results, has probably deterred geologists from attempting the task, especially as large areas are very imperfectly known.

BERNARD HOBSON

Tapton Elms, Sheffield, December 24

THE first part of Mr Hobson's letter alone requires notice from me, as the latter part characterizes as absurd the views of those eminent geologists who have estimated the total thickness of the sedimentary rocks, and seems to assume that such writers as the late Dr Croll and Sir Andrew Ramsay overlooked the very obvious considerations he sets forth.

As regards myself, he reiterates the statement that when geologists have estimated the total thickness of the sedimentary rocks at 177,200 feet, they mean that this amount of sediment has covered the whole land surface of the globe, that, for example, the coal measures, the lias, the chalk, the greensand, the London clay, &c, &c, were each deposited over the whole of the continents, since it is by adding together the thicknesses of these and all other strata that the figure 177,200 feet (equal to 33 miles) has been obtained.

Mr Hobson concludes with what he seems to think is a *reductio ad absurdum*—"Dr Wallace's calculation leads to the absurd result that continents are growing nineteen times as fast as materials are produced to supply their growth."

But the apparent absurdity arises from the absence of any definition of the "growth of continents," and also from supposing that the growth of continents is the problem under discussion. The question is, as to the growth in thickness, of sedimentary deposits such as those which form the geological series. These deposits are each laid down on an area very much smaller than the whole surface of the continent from the denudation of which they are formed. They are therefore necessarily very

much thicker than the average thickness of the denuded layer and the ratio of the area of denudation to the area of deposition which I have estimated at 19 to 1, gives their proportionate thickness. If Mr Hobson still maintains that he is right, he can only prove it by adducing evidence that every component of the series of sedimentary rocks has once covered the whole land surface of the globe, not by assuming that it has done so, and characterizing the teaching of all geologists to the contrary as absurd.

ALFRED R. WALLACE

### Ancient Ice Ages

MR READE in his letter (NATURE, p. 174) refers to the striations on the pebbles forming the conglomerates at Abberley and the Clent Hills.

Following the late Sir Andrew Ramsay, he considers the deposits to be of glacial origin, but goes further than that distinguished geologist in citing them as proof of a former ice age.

It is but reasonable to suppose that glaciers existed in past ages in places where the conditions—such as high altitude and abundant precipitation—were favourable.

Before, however, the existence of a former glacial period can be established, we must have evidence of contemporaneous deposits of undoubtedly glacial origin, and extending over wide spread areas—say half a hemisphere.

### Printing Mathematics

THE use of the solidus in printing fractions has been advocated by authorities of such weight that it seems almost a heresy to call it into question. Yet I venture to think that there is a good deal to be said against it. In such matters the course preferred by mathematical writers and their printers is apt to take precedence over that which is most convenient for the great body of those who will read their work. It is tacitly assumed by those who prefer this notation that the getting of mathematical formulae into line with ordinary printing is an unmixed advantage. No doubt it is easier to set up the work in type thus, but with the consequent rapidity and cheapness of printing the advantage ends. Most people will agree that it is much pleasanter to read a mathematical book in which the letterpress is well spaced, so that the formula stand out clearly from the explanatory language, than one in which the two run together in an unbroken stream just as a book divided into paragraphs is more readable than one which is not. The old style is more restful to the mind and eye and one can more readily pick out the salient features of the demonstration.

Another aspect of the question seems to me more important. In making any calculation mentally it is much easier to visualize fractions, more especially if complicated, as written in the ordinary way than as written with the new-fashioned notation. The component parts of the mental picture are imagined as spread over a plane instead of being arranged along a line, and can be thought of separately with less confusion. From a similar point of view it will be admitted that it is inconvenient to write mathematical expressions in one form and to print them in another.

Then, again, I doubt whether the assumption that the solidus notation conduces to accuracy is justified. No doubt the printer makes fewer original errors, but whereas with the old notation his frequent glaring errors are more readily detected by the proof-reader (or, if missed by him, by the ordinary reader), with the new notation the misplacement or omission of a solidus is, from the simplicity of the error, likely to be overlooked. In general, no one will be the poorer if a little more trouble is taken with the printing, and a little more paper is used for the book.

The symbol  $\frac{\quad}{\quad}$  has advantages over its equivalent  $\frac{\quad}{\quad}$ , and to its restricted use, such as is made by Sir G. Stokes, one can hardly object, it matters little how such expressions as  $a/b$  or  $dy/dx$  are printed. But it is the thin end of the wedge, and one is under a debt of gratitude to Mr Cassie for showing, in your issue of November 3, to what it may lead. May it be a long time before we have to learn to substitute for the harmless expression,

$\frac{b}{c(d+e)}$  its newest equivalent,  $b \setminus c / (d + e) \setminus 3$ !

I trust that no one will interpret the final note of exclamation as a factorial symbol.

### The Teaching of Botany

I do not think there is at present any book in English giving practical instructions for experiments in Physiological Botany. There is, however, an excellent book of this kind in German, Dr W Detmer's "Das pflanzen physiologische Praktikum," published by Gustav Fischer, Jena, 1888. This, no doubt, contains all that your correspondent "A II" (*NATURE*, ante, p. 151) requires, though it is perhaps somewhat more advanced than is necessary for school teaching. D II SCOTT  
Old Palace, Richmond, Surrey

### THE ORIGIN OF THE YEAR<sup>1</sup>

IV

THE reformation of the Egyptian calendar, to be gathered, as I suggested in my last article, from the decree of Tanis, is not, however, the point to which reference is generally made in connection with the decree. The attempt recorded by it to get rid of the vague year is generally dwelt on.

Although the system of reckoning which was based on the vague year had advantages with which it has not been sufficiently credited, undoubtedly it had its drawbacks.

The tetramenes, with their special symbolism of flood, seed, and harvest time, had apparently all meant each in turn, however, the meanings of the signs were changed, the "winter season" occurred in this way in the height of summer, the "sowing time" when the whole land was inundated, and there was no land to plant, and so on. Each festival, too, swept through the year. Still, it is quite certain that information was given by the priests each year in advance, so that agriculture did not suffer, for if this had not been done, the system, instead of dying hard, as it did, would have been abolished thousands of years before.

Before I proceed to state shortly what happened with regard to the fixing of the year, it will be convenient here to state a suggestion that has occurred to me, on astronomical grounds, with regard to the initial change of year.

It is to be noted that in the old tables of the months, instead of Sirius leading the year, we have Text with the two feathers of Amen. In later times this is changed to Sirius.

I believe it is generally acknowledged that the month tables at the Ramesseum is the oldest one we have, there is a variant at Edfu. They both run as follows, and no doubt they had their origin when a 1st Thoth coincided with an heliacal rising and Nile flood.

Egyptian month	Tropical month	Ramesseum	Edfu
Thoth	June-July	Text	Tex
Phaophi	July-Aug	Ptah (Ptah-res-aneb-f)	Ptah (Menx)
Athyr	Aug-Sep	Hathor	?
Choiak	Sep-Oct	Paxt	Kehek
Tybi	Oct-Nov	Min	Set but
Mechir	Nov-Dec	Jackal (rekh-ur)	Hippopotamus (rekhur)
Phamenoth	Dec-Jan	.. (rekh-netches)	Hippopotamus (rekh netches)
Pharmuthi	Jan-Feb	Rennuti	Renen
Pachon	Feb-Mar	xensu	xensu
Payni	Mar-Apr	Horus (xont)	Horus (Hor-xent xali)
Epiphi	Apr-May	Apet	Apet
Mesori	May-June	Horus (Hor-m-xut)	Horus (Hor-ra-m-xut)

I am informed that Text, in the above month-list, has some relation to Thoth. In the early month-list the goddess is represented with the two feathers of Amen, and in this early stage I fancy we can recognize her as

<sup>1</sup> Continued from p. 35

Ament, but in later copies of the table the symbol is changed to that of *Sirius*. This, then, looks like a change of cult depending upon the introduction of a new star—that is, a star indicating by its heliacal rising the Nile rise after the one first used had become useless for such a purpose.

I have said that the Ramesseum month list is probably the oldest one we have. It is considered by some to date only from Ramses II, and to indicate a fixed year, such, however, is not Krall's opinion.<sup>1</sup> He writes—

"The latest investigations of Dumichen show that the calendar of Medinet Abu is only a copy of the original composed under Ramses II about 120 years before

"But the true original of the calendar of Medinet-Abu does not even date from the time of Ramses II. It is known to every Egyptologist how little the time of the Ramessids produced what was truly original, how much just this time restricted itself to a reproduction of the traditions of previous generations. In the calendar of Medinet-Abu we have (p. 48) not a fixed year instituted under Ramses II, but the normal year of the old time, the vague year, as it was, to use Dschewhari's words quoted above (p. 852), in the first year of its institution, the year as it was before the Egyptians had made two unwelcome observations. First, that the year of 365 days did not correspond to the reality, but shifted by one day in four years with regard to the seasons, secondly—which of course took a much longer time—that the rising of Sirius ceased to coincide with the beginning of the Nile flood.

"We are led to the same conclusion by a consideration of the festivals given in the calendar of Medinet-Abu. They are almost without exception the festivals which we have found in our previous investigation of the calendars of Esne and Edfu to be attached to the same days. We know already the Uaja festival of the 17th and 18th Thoth, the festival of Hermes of the 19th Thoth, the great feast of Amen beginning on the 19th Paophi, the Osiris festivals of the last decade of Choiak, and that of the coronation of Horus on the 1st Tybi.

"Festivals somehow differing from the ancient traditions, and general usage are unknown in the calendar of Medinet-Abu, and it is just such festivals which have enabled us to trace fixed years in the calendars of Edfu and Esne.

"We are as little justified in considering the mythological-astronomical representations and inscriptions on the graves of the time of the Ramessids as founded on a fixed year, as we can do this in the case of the Medinet-Abu calendar. In this the astronomical element of the calendar is quite overgrown by the mythological. Not only was the daily and yearly course of the sun a most important event for the Egyptian astronomer, but the priest also had in his sacred books many mythological records concerning the god Râ, which had to be taken into account in these representations. The mythological ideas dated from the oldest periods of Egyptian history, we shall, therefore, be obliged for their explanation not to remain in the 13th or 14th century before Christ, but to ascend into previous centuries. *I should think about the middle of the fourth millennium before Christ, that is the time at which the true original of the Medinet-Abu calendar was framed.* Further we must in these mythological and astronomical representations not overlook the fact that we cannot expect them to show mathematical accuracy—that, on the contrary, if that is a consideration, we must proceed with the greatest caution. We know now how inexact were the representations and texts of tombs, especially where the Egyptian artist could suppose that no human eye would inspect his work, we also know how often representations stop short for want of room, and how much the contents were mutilated for the sake of symmetry."

<sup>1</sup> *Op cit* p. 42.

There is also, as I have indicated, temple evidence that Sirius was not the first star utilized as a herald of sunrise. We have then this possibility to explain the variation from the true meaning of the signs in Ramessid times

			
Pre-Sirian Text	Thoth Phaophi Athyr Choiak Tybi Mekhir Phamenoth Pharmouthi Pachons Payni Epiphi Mesori	Thoth Phaophi Athyr Choiak Tybi Mekhir Phamenoth Pharmouthi Pachons Payni Epiphi Mesori	Thoth Phaophi Athyr Choiak Tybi Mekhir Phamenoth Pharmouthi Pachons Payni Epiphi Mesori
Sirian, 3192 B.C.			

And it may be gathered from this that the Calendar was reorganized<sup>1</sup> when the Sirius worship came in and that the change effected in 619 B.C. brought the hieroglyphic signs back to their natural meaning and first use.

Before I pass on it may be convenient in connection with the above month-tables to refer in the briefest way to the mythology relating to the yearly movement of the sun, in order to show that when this question is considered at all, if it helps us with regard to the mythology connected with the rising and setting of stars, it will as assuredly help us with regard to the mythology of the various changes which occur throughout the year.

We have, as we have seen, in the Egyptian year really the prototype of our own. The Egyptians, thousands of years ago, had an almost perfect year containing twelve months, but instead of four seasons they had three, the time of the sowing, the time of the harvest, and the time of the inundation. Unfortunately, at various times in Egyptian history, the symbols for the tetramenes seem to have got changed.

The above-given inscriptions show that they had a distinct symbolism for each of the months. Gods or goddesses are given for ten months out of the twelve, and where we have not these, we have the hippopotamus (or the pig) and the jackal, two circumpolar constellations. I think there is no question that we are dealing here with these constellations, though the figures have been supposed to represent something quite different.

There are also myths and symbols of the twelve changes during the twelve hours of the day, the sun being figured as a child at rising, as an old man when setting in the evening. These ideas were also transferred to the annual motion of the sun. In Macrobius, as quoted by Krall, we find the statement that the Egyptians compared the yearly course of the sun also with the phases of human life.

Little child	=	Winter solstice
Young man	=	Spring equinox
Bearded man	=	Summer solstice
Old man	=	Autumnal equinox

With the day of the summer solstice the sun reaches the greatest northern rising amplitude, and at the winter solstice its greatest southern amplitude. By the solstices the year is divided into two approximately equal parts, during the one the points of rising move southwards, during the other northwards.

This phenomenon, it is stated, was symbolized by the two eyes of Ra, the so-called Uthats, which look in different directions. They appear as representing the sun in the two halves of the year.

We have next to discuss the fixed year, to which the Egyptian chronologists were finally driven in later Egyptian times.

The decree of Tanis was the true precursor of the

<sup>1</sup> Goodwin has already asked, "Does the Smith Papyrus refer to some rectification of the Calendar made in the 4th Dynasty, similar to that made in Europe from the old to the new style," quoted by Riel, "Sonnen und Sirius-Jahr," p. 361.

Julian correction of the calendar. In consequence of this correction we now add a day every four years to the end of February. The decree regulated the addition, by the Egyptians, of a day every four years by adding a day to the epacts, which were thus 6 every four years instead of being always 5 as they had been before.

In fact it replaced the vague year by the sacred year long known to the priests.

But if everything had gone on then as the priests of Tanis imagined, the Egyptian new year's day, if determined by the heliacal rising of Sirius, would not always afterwards have been the 1st of Payni, although the solstice and Nile flood would have been due at Memphis about the 1st of Pachons, and this is, perhaps, one among the reasons why the decree was to a large extent ignored.

Hence, for some years after the date of the decree of Tanis there were at least three years in force: the new fixed year, the new vague year, reckoning from Pachons, and the old vague year, reckoning from Thoth.

But after some years another attempt was made to get rid of all this confusion. The time was 23 B.C., 216 years after the decree of Tanis, and the place was Alexandria. Hence the new fixed year introduced is termed the Alexandrine year.

This new attempt obviously implied that the first one had failed, and the fact that the vague year was continued in the interval is sufficiently demonstrated by the fact that the new year was  $4\frac{1}{4}$  - 54 days *in retard*. In the year of Tanis it is stated that the 1st Pachons, the new New Year's Day, the real beginning of the flood, fell on the 19th of June (Gregorian), the summer solstice, and hence the 1st of Thoth fell on the 22nd of October (Gregorian). In the Alexandrine year the 22nd of October is represented by the 29th of August, and the 19th of June by the 20th of April.

It is noteworthy that in the Alexandrine year the heliacal rising of Sirius on the 23rd of July (Julian) falls on the 29th of Epiphi, nearly the same date as that to which I first drew attention in the inscriptions of the date of Ihotmes and Pepi. This, however, it is now clearly seen, is a pure accident, due to the break of continuity before the Tanis year, and the *slip* between that and the Alexandrine one. It is important to mention this, because it has been thought that somehow the "Alexandrine year" was in use in Pepi's time.

It would seem that the Alexandrine revision was final, and that the year was truly fixed, and from that time to this it has remained so, and must in the future for ever remain so. It must never be forgotten that we owe this perfection to the Egyptians.

One of the chief uses of the Egyptian calendar that has come down to us was the arrangement and dating of the chief feasts throughout the year in the different temples.

The fact that the two great complete feast calendars of Edfu and Esne refer to the only fixed years evidenced by records, those of Tanis and Alexandria, one of which was established over 200 years after the other, is of inestimable value for the investigation of the calendar and chronology of ancient Egypt.

In an excellent work of Brugsch, "Three Festival Calendars from the Temple of Apollinopolis Magna (Edfu) in Upper Egypt," we have two calendars which we can refer to fixed years, and can date with the greatest accuracy. In the case of one of these, that of Esne, this is universally recognized, as to the other, that of Apollinopolis Magna, we are indebted to the researches of Krall, who points out, however, that "it is only when the province of Egyptian mythology has been dealt with in all directions, that we can undertake a successful explanation of the festival catalogues. Even externally they show the greatest eccentricities, which are not diminished but increased on a closer investigation."

About some points, however, there is no question. The summer solstice is attached in the Edfu calendar to the 6th Pachons, according to Krall, while the beginning of the flood is noted on the 1st of that month. In the Esne calendar, the 26th Payni is New Year's Day. We read — "26th Payni, New Year's Day, Feast of the Revelation of Kahi in the Temple. To dress the crocodiles, as in the month of Mechir, day 8."

Peculiar to the Esne calendar, according to Krall, is the mentioning of the "New Year's Festival of the Ancestors" on the 9th of Thoth, to the Edfu calendar, publication No. 1 of Brugsch, the festival "of the offering of the first of the harvested fruits, after the precept of King Amenemha I., on the 1st Epiphi, and "the celebration of the feast of the great conflagration" on the 9th of Mechir. In feast calendar No. 1, the reference to the peculiar Feast of Set, is also remarkable, this was celebrated twice, first in the first days of Thoth (? 9th?), then, as it appears, in Pachons (10th). This feast is well known to have been first mentioned under the old Pharaoh Pepi Merinra.

It is a question whether in the new year of the ancestors and the feasts of Set, all occurring about the 9th Thoth and Pachons, we have not Memphis Festivals which gave way to Theban ones, for so far as I can make out the flood takes about nine days to pass from Thebes to Memphis, so that in Theban time the arrival of the flood at Memphis would occur on 9th or 10th Thoth. There is no difficulty about the second dating in Pachons, for as we have seen this followed on the reconstruction of the calendar.

It is also worthy of note that the feast of the "Great Conflagration" took place very near the Spring Equinox.

It is well to dwell for a moment on the Edfu inscriptions to see if we can learn from them whether they bear out or not the views brought forward with regard to this reconstruction.

As we have seen it is now acknowledged that the temple inscriptions at Edfu (which are stated to have been cut between 117 and 81 B.C.) are based upon the fixed year of Tanis, hence we should expect that the rising of Sirius would be referred to on 1 Payni, and this is so. But here, as in the other temples, we get double dates referring to the old calendars, and we find the "wounding of Set" referred to on the 1st Epiphi and the rising of Sirius referred to under 1 Messori. Now this means, if the old vague year is referred to, as it most probably is, that

5 Epacts  
30 Messori

—  
 $35 \times 4 = 140$  years

had elapsed since the beginning of a Sothic cycle, when the calendar coincidences were determined, which were afterwards inscribed on the temple walls. We have, then, 140 years to subtract from the beginning of the cycle in 270 B.C. This gives us 130 B.C., and it will be seen that this agrees as closely as can be expected with my view, whereas the inscription has no meaning at all if we take the date given by Censorinus.

I quote from Krall<sup>1</sup> another inscription common to Edfu and Esne, which seems to have astronomical significance.

"1 Phamenot Festival of the suspension of the sky by Ptah, by the side of the god Harschaf, the master of Heracleopolis Magna (Ai) Festival of Ptah. Feast of the suspension of the sky (Es).

"Under the 1st Phamenot, Plutarch, de Iside ac Osiride c. 43, b, notices the ἑμβασίς Ὀσίριδος εἰς τὴν σελήνην. These are festivals connected with the celebration of the winter solstice, and the filling of the Uza-

eye on the 30th Mechir. Perhaps the old year, which the Egyptians introduced into the Nile valley at the time of their immigration, and which had only 360 days, commenced with the winter solstice. Thus we should have in the 'festival of the suspension of the sky,' by the ancient god Ptah—venerated as creator of the world—a remnant of the time when the winter solstice marked the beginning of the year, and also the creation."

The reconstruction of the calendar naturally enhanced the importance of the month Pachons, this comes out very clearly from the inscriptions translated by Brugsch. On this point Krall remarks —

"It is therefore quite right that the month Pachons, which took the place of the old Thoth by the decree of Tanis, should play a prominent part in the feast calendars of the days of the Ptolemies, and the first period of the Empire in general, but especially in the Edfu calendar, which refers to the Tanitic year. The first five days of Pachons are dedicated in our calendar to the celebration of the subjection of the enemies by Horus, we at once remember the above mentioned (p. 7) record of Edfu of the nature of a mythological calendar, describing the advent of the Nile flood. On the 6th of Pachons—remember the great importance of the sixes in the Ptolemaean records—the solstice is then celebrated. The Uza-eye is then filled, a mythical act which we have in another place referred to the celebration of the solstice, and "everything is performed which is ordained" in the book "on the Divine Birth."

Next let us turn to Esne. The inscriptions here are stated to be based on the Alexandrian year, but we not only find 1st Thoth given as New Year's Day, but 26 Payni given as the beginning of the Nile flood.

Now I have already stated that the Alexandrine year was practically a fixing of the vague Tanis year; that is, a year beginning on 1st Pachons in 239 B.C.

If we assume the date of the calendar coincidences recorded at Esne to have been 15 B.C. (we know it was after 23 B.C. and at the end of the Roman dominion), we have as before, seeing that, if the vague Tanis year had really continued, it would have swept forward with regard to the Nile flood,

Pachons 30  
Payni 26

—  
 $56 \times 4 = 224$  years after 239 B.C.

This double dating, then, proves the continuation of the vague year of Tanis if the date 15 B.C. of the inscription is about right.

Can we go further and find a trace of the old cycle beginning 270 B.C.? In this case we should have the rising of Sirius

270  
— 15

—  
4255 years

—  
64 = say 5 Epacts and 2 months

This would give us 1 Epiphi. Is this mentioned in the Esne calendar? Yes, it is, "1 Epiphi. To perform the precepts of the book on the second divine birth of the child Kahi."

Now the 26th Payni, the new New Year's Day, is associated with the "revelation of Kahi," so it is not impossible that "the second divine birth" may have some dim reference to the feast.

It is not necessary to pursue this intricate subject further in this place, so intricate is it that, although the suggestions I have ventured to make on astronomical grounds seem consistent with the available facts, they are suggestions only, and a long labour on the part of Egyptologists will be needed before we can be said to be on firm ground.

J. NORMAN LOCKYER.

<sup>1</sup> On the 20th Epiphi of the 10th year of Ptolemy III the ceremony of the stretching of the cord took place. Dilmacher, *Adg. Z.* 2, 1872, p. 41.

## PROPOSED HANDBOOK TO THE BRITISH MARINE FAUNA

THE admirable monographs issued under the auspices of the Ray Society, and in Van Voorst's series, by such well-known authorities as Forbes and Hanley, Alder and Hancock, M'Intosh, Allman, Hincks, Brady, Norman, and others, are amongst the most creditable and useful productions of British Zoology, and all naturalists must devoutly trust that there are still others of a like classical nature to follow, and that, for example, Prof. M'Intosh will soon be able to complete his long-expected work on the British Polychæta.

But many Marine zoologists feel that, quite apart from such exhaustive and expensive monographs, and only aspiring to occupy a very much humbler position, there is pressing need of a "pocket" or seaside "Invertebrate Fauna," which could be used in much the same way as the botanists' "Field Flora." It has been suggested to me more than once during the last few years that I would be doing useful work in compiling such a book, and as no one else seems ready or willing to do so, I feel inclined to make the attempt. Some material has already been accumulated for the purpose, but before going further I wish to lay my views before my fellow zoologists, in the hope that they will be kind enough to criticize the scheme and give me the benefit of their advice.

The only existing work of the kind is Gosse's well-known, and so far as it goes, very excellent little "Manual of Marine Zoology," but that book does not really meet the present want, as not only is the date of publication 1855-6, since when the number of genera and species has probably been something like doubled, but also Gosse merely gives the names of the species, while the book I think of would, in order to be of any real use, require to aim at giving a brief but sufficient diagnosis and figure of every British species. I would adopt as "British" the area defined by Canon Norman's British Association Committee in 1887.

Probably the most convenient form of publication would be some four to six small volumes, each dealing with one or two of the large groups. This would allow of the groups being published as they were ready, not necessarily in zoological order, and would also be convenient for the use of those interested in one set of animals.

There would be definitions—perhaps with occasional analytical tables or keys—of orders, families, &c., down to and including genera. Under each genus would be given all sufficiently defined species with a brief description of each either in tabular form or in series, as seems most suitable in each case, and with an indication of size, range, and habitat. Many species might be described very briefly in terms of preceding species, the differences merely being pointed out. By simplicity of language, avoidance of unnecessary repetition, and use of contractions it might be hoped that each species could be confined on an average to a couple of lines.

Illustrations would be either in the form of numerous small outline figures on thin paper plates inserted as near as possible to the pages where the descriptions occur, or as small groups of cuts (as in "Gosse") in the text. There would be a figure of the whole animal in each important genus, or small family, and the figures of the species would represent the diagnostic points only, e.g. in the zoophytes there would be a figure in the genus *Plumularia* of an entire colony, or shoot, while the species *pinnata*, *setacea*, *catharina*, &c., would be represented each by a small figure showing the pinnæ, calyces, or nematophores as the case required.

I shall now give a few examples, taken from different groups, of the method in which the genera and species might be treated, in order that specialists may have the opportunity of judging and criticizing.

NO. 1210, VOL. 47]

- I From Cœlenterata.—Genus ANTENNULARIA  
Stems simple or branched, pinnæ verticillate, nematophores along the stems gonothecæ axillary, unilateral  
*A. antennaria*, L., stems clustered, usually simple, hydrothecæ separated by 2 joints 6 to 9 in high Gen distr deep w  
*A. ramosa*, Lamk., stems single, usually branched, hydrothecæ separated by 1 joint only 6 to 9 in high Gen distr deep w
- II From Crustacea.—Family MAJIDÆ  
HYAS Carapace tuberculous, no spines, branches of rostrum not divaricated, second joint of antenna dilated, no teeth beneath last joint of walking legs  
*H. araneus*, L., carapace not contracted behind post-orbital process 3 in Common, shallow  
*H. coarctatus*, Leach, carapace contracted behind post-orbital process 1 in Gen distr shallow
- PISA Carapace may be tuberculous, with strong postero-lateral spine branches of rostrum divaricated at extremity, second joint of antenna slender, terminal joint of walking legs toothed beneath  
*P. tetrastodon*, Leach, carapace with small tubercles, antero-lateral margin with 4 spines 2 in Rare, S coast  
*P. gibbosa*, Leach, carapace with large rounded elevations, but no tubercles, no spines on antero-lateral margin Rare, deep w, S coast
- MAIA Carapace covered with numerous sharp spines, branches of rostrum strongly divaricated, no teeth beneath terminal joint of walking legs  
*M. squinado*, Latr 10 in long S and W coasts of England
- III From Tunicata.—Family MOIGUIIDÆ  
FUCYRA Branchial sac with no folds  
*F. glutinosa*, Moll., circular area on side free from sand ½ in Shallow w, gen distr  
*F. globosa*, Hanc., entirely covered with sand ½ in
- PERA Bran s with 5 folds each side  
*P. hancocki*, Hrdn., matted fibres at poster end ½ in Irish Sea, 20 fms
- MOIGUIA Bran s with 6 or 7 folds each side  
*M. inconspicua*, A & H, 6 folds, sandy, dors lam entire, no pap on stigmata ½ in  
*M. impura*, Hel., 6 folds, sandy, small papilla on edges of stigmata 1 in W of Ireland, shallow  
*M. simplex*, A & H, few hairs, little or no sand, 6 folds, anus fringed, dors tub horse shoe, aperture to left ½ in  
*M. tubifera*, Orst., 6 folds, anus fringed, dors tub horse shoe, dors lam toothed, sandy 1 in E coast  
*M. ampullacea*, v Ben, 6 folds, anus fringed, dors tub horse shoe, 3 bars on fold, dors lam entire 1 in E coast, shallow  
*M. socialis*, Ald., 6 folds, anus fringed, dors tub horse shoe, 4 bars on fold, dors lam entire, sandy, gregarious ½ in shallow w S coast  
*M. holstiana*, Hrdn., 6 folds, dors tub serpentinif, hairs but little sand on test ½ in W of Ireland, 10 fms  
*M. oculata*, Kupf., 7 folds, dors tub horse shoe, dors lam toothed, whole body sandy 1 in Shallow w S and W coasts  
*M. oculata*, Forb., 7 folds, siphonal region alone free from sand, and retractile between folds of test 1 in Gen distr Shallow w  
*M. capiformis*, Hrdn., 7 folds, globular, not attached, no sand ¾ in S coast, shallow w  
*M. curvica*, A & H, 7 folds, attached by left side, no sand ¼-½ in under st, litt E and W coasts
- CYCNICELLA, as MOIGUIA, but branchial and atrial lobes facinated  
*C. complanata*, A & H, 6 folds on left, 7 on right, depressed attached, sandy, ¼ in

In conclusion, I need scarcely say that I shall be very grateful for suggestions, and, if the work is carried on, for any information from specialists about less known species, and the discrimination of allied forms, and for specimens, and also for references to any descriptions which might be likely to escape my notice.

W A HERDMAN

## NOTES

IN consequence of the unavoidable absence abroad of the new President of the Institution of Electrical Engineers, Mr W H Preece, F R S, on the 12th inst, he will deliver his inaugural address on the 26th inst.

A PUBLIC meeting, arranged by the Technical Instruction Committee of the Essex County Council, will be held in the Shire Hall, Chelmsford, on Friday afternoon, January 13, at 4.30 p m, Lord Rayleigh in the chair. An address will be given by Sir Henry E Roscoe on technical instruction in agricultural counties, with especial reference to science teaching. Afterwards a discussion will take place.

DR PERCY RENDALL, F Z S, has accepted an appointment as Resident Medical Officer to the Sheba Gold-mining Company in the Barberton District of the Transvaal. He will reside at Eureka City, at an elevation of 5000 feet above the sea level. Dr. Rendall made a good collection of birds during his recent residence at Bathurst on the Gambia, of which he has given an account in the *Ibis* for last year (*Ibis*, 1892, p. 215). He has also made many valuable donations to the Zoological Society's Menagerie, amongst which is the unique example of the Nagor Antelope (*Cervicapra redunca*), presented by him in June, 1890. Of this scarce animal there is, we believe, no example in the British Museum. Dr. Rendall's new appointment will give him many opportunities of extending our zoological knowledge of a little known district.

LORD WALSINGHAM, who has devoted much of his attention to the micro-lepidoptera, has filled the vacancy on the staff of the *Entomologists' Monthly Magazine*, occasioned by the death of Mr Stainton.

LAST week a preliminary meeting was held at the house of Sir James Paget to consider what steps should be taken with regard to a memorial of Sir Richard Owen. It was decided that a committee should be formed to make the necessary preparations. The following, among others, have consented to serve as members.—The Presidents of the Royal Colleges of Physicians and Surgeons and of most of the scientific societies, the Duke of Teck, Lord Playfair, Prof. Huxley, Sir Joseph Hooker, Sir Henry Acland, Sir John Evans, Dr Michael Foster, Mr Slater, Sir W Savory, Mr. Hulke, Sir Joseph Fayrer, Sir Edward Fry, Dr Günther, Mr Carruthers and Dr H Woodward. Sir William Flower will act as treasurer, and a general meeting will shortly be called. It has been suggested that the memorial should be a marble statue, to be placed in the hall of the Natural History Museum.

PROF WESTWOOD, who died on Monday at the age of eighty-seven, will be greatly missed at Oxford. To most people he is known chiefly as a writer on the archæology and palæography of art, but he was equally eminent as an entomologist. He was one of the founders of the Entomological Society, and received one of the Royal Society's gold medals for his entomological researches.

WE regret to record the death of General Axel Wilhelmsvitch Gadolin, an old member of the Russian Academy of Sciences. He was born of Finnish parents on July 10, 1828, received his education in the Finnish Corps of Cadets, and till his death remained in the Russian Artillery, devoting his leisure time to mineralogical, and especially to mathematical, researches into the molecular forces which act in the formation of crystals. One of his earlier works, published in the *Verhandlungen der Mineralogischen Gesellschaft zu St. Petersburg*, was on some minerals from Pitkaranta. His chief work, published in 1867, was his "Deduction of all the Systems of Crystals and their Derivates from a Unique Principle." A deep impression was

produced upon the members of the Russian Mineralogical Society by Gadolin's first communication upon this subject. The lucidity with which he deduced all systems of crystallization from fundamental principles of equilibrium of molecular forces, and the simplicity of the exposition of his researches, entirely based upon high mathematical analysis, reminded his hearers of some of the best pages of Laplace's writings. The work soon became widely known in a German translation. A paper on the resistance of the walls of a gun to the pressure of gunpowder gases also deserves mention, as, in addition to the formerly known formulæ of highest resistance of cylinders, he gave a new formula of minimal resistance. Later on his method was used with great success by Klebsch, in his well-known "Theorie der Elasticität fester Körper," for deducing some general equations of equilibrium of solid bodies.

THE last issue of the *Izvestia* of the East Siberian Geographical Society (vol. xxiii. 3) contains an obituary notice by V. Obrutcheff, of I. D. Chersky, who died in the far north east of Siberia, during his expedition to the Kolyma river, after having given many years of his life to the active geological exploration of Siberia. He began his work in 1872 at Omsk, where he made most valuable discoveries of post-tertiary mammals. During the next two years he explored the Tunka and Kitoi Alps, but his rich materials were lost during the great conflagration at Irkutsk in 1879. In 1875 and 1876 he explored the Nijneudinsk caves, making again remarkable finds of quaternary mammals, and then he gave fully five years to the study of the stores of Lake Baikal, embodying the results of his extensive researches in a map (6.7 miles to the inch), and in vol. xii of the *Memoirs* of the East Siberian Society, and vol. xv of the *Memoirs* of the Russian Geographical Society. In 1882 and 1883 he explored the Lower Tunguska, and again made rich finds of fossil mammals. The next five years he spent at the Academy of St. Petersburg, preparing the part of Ritter's "Asia" which is devoted to Lake Baikal, and working out the rich materials collected by another lamented Polish explorer of East Siberia, Czekanowski. He also worked out the collections brought in from the New Siberia Islands by MM. Bunge and Toll, and came to such interesting and new conclusions as to the recent geological history of Arctic Siberia, that the Academy of Sciences sent him out in 1891, at the head of a new expedition to the Kolyma region. There he died, in the midst of his promising work.

THE twentieth annual dinner of the old students of the Royal School of Mines will be held at the Holborn Restaurant, on Tuesday, January 10, at 7 o'clock. The chair will be taken by Mr W. Gowland, late of the Imperial Mint, Osaka, Japan.

MR G. T. ATKINSON has been appointed Professor of Cryptogamic Botany at Cornell University, Ithaca, State of New York, in the place of Prof. W. R. Dudley, who has gone to the Leland Stanford University, Palo Alto, California.

AT the next public meeting of the French Academy, in December 1893, forty-five prizes will be awarded for the best work tending to the advancement of the various branches of science. Of these, the following are, by the terms of the bequests, open to competitors of all nationalities. The Prix Lalande will be awarded for the most interesting observation, or the memoir or work most useful for the progress of Astronomy. Its value is 540 francs. The Prix Valz, of 460 francs, is offered under the same conditions. Three prizes of 10,000 francs each, bequeathed by M. L. La Caze, will be awarded annually for the best contributions to Physiology, Physics, and Chemistry respectively. The Prix Tchibatchef, of 3000 francs, is offered annually to naturalists who have distinguished themselves most in the exploration of the continent of Asia or the adjacent isles.

excluding better known regions such as British India, Siberia proper, Asia Minor, and Syria. The explorations must have some object connected with Natural Science, physical or mathematical, and will not be awarded for archaeological or ethnographic work. All these prizes will be awarded in December 1893. Works for competition to be sent in to the *Secrétaire* before June 1. The Prix Leconte, of 50,000 francs, for the most important scientific discovery, will be awarded in 1895.

THE Royal Academy of Sciences of Turin, in accordance with the will of Dr. Cesare Alessandro Bressa, and in conformity with the programme published December 7, 1876, announces that the term for competition for scientific works and discoveries in the years 1889-92, to which only Italian authors and inventors were entitled, was closed on December 31, 1892. The ninth Bressa prize will be given to the scientific author or inventor, whatever be his nationality, who during the years 1891-94, "according to the judgment of the Royal Academy of Sciences of Turin, shall have made the most important and useful discovery, or published the most valuable work on physical and experimental science, natural history, mathematics, chemistry, physiology and pathology, as well as geology, history, geography and statistics." The term will be closed at the end of December 1894. The sum fixed for the prize, income tax being deducted, is 10,416 francs. Any one who proposes to compete must declare his intention within the time above mentioned, by means of a letter addressed to the President of the Academy, and send the work he wishes to be considered. The work must be printed. Works which do not obtain the prize will be returned to the authors, when asked for within six months from the adjudication of the prize. None of the national members, resident or not resident, of the Turin Academy can obtain the prize. The Academy gives the prize to the scientific man considered most worthy of it, even if he has not competed.

MESSRS. MACMILLAN AND CO. hope to publish early in the spring the second volume of Dr. Arthur Gamgee's *Treatise on Physiological Chemistry*. This volume, which deals with the Digestive Processes, will be followed at no long interval by an enlarged and revised edition of the first volume, which originally appeared in 1880.

THE United States Government is inviting the various European Governments to send delegates to an International Conference of Meteorologists, to be held at Washington. The following is said to be proposed as a provisional programme of topics to be discussed by the Conference: (a) The organization of additional meteorological work for the benefit of agriculture. (b) The extension to all ports frequented by commerce of the benefits of systematic storm and weather signals, and the introduction of a uniform system of storm warnings throughout the world. (c) The co-operation of all nations in the publication of a daily chart of the weather over all the habited lands and frequented oceans for the study of the atmosphere as a whole, and as preparatory to the eventual possibility of predicting important changes several days in advance. (d) The equitable apportionment of stations, publications, and expenses among the nations, and the suggestion of practical methods by which to secure observations from those countries that are not represented in this Conference. (e) The encouragement by the respective Governments of special scientific investigations looking to the advancement of meteorology. Such other matters as the delegates may think advisable to submit for discussion, or for future report, will also be considered.

DURING the past week the sharp frost has continued almost uninterruptedly over these islands, with the exception of a partial thaw on Friday and Saturday, caused by a disturbance in the west spreading to the eastward. The greatest increase of temperature occurred in the north and west, but in the south-east of

England the day readings were only slightly above the freezing-point. There was a complete change in the type of weather at the close of the week, a large anticyclone had formed over Scandinavia, and the air over nearly the whole of Europe was intensely cold, the minimum in the shade at Haparanda on Sunday registering 72° below the freezing-point, and the barometer on subsequent days rose to 31 inches and upwards in these islands. These conditions were accompanied by cold easterly gales in the south-west of England, while a heavy fall of snow was experienced in the south-eastern districts. On the coast of Kent the shade minimum fell to 11° during Monday night. The *Weekly Weather Report* issued on December 31 shows that the temperature of that period was much below the mean, amounting to 9° or 10° over the greater part of England, and to 12° in the Midland counties. Very little rain fell during the week, the deficiency of rainfall in the south-western district of England for the last year amounts to 10.8 inches, or more than 25 per cent. below the average of the 25 years 1866-90. A good deal of fog was experienced at the inland stations during the week.

SOME very interesting entomological notes from the Eastern Archipelago are given by Mr. J. J. Walker in the January number of the *Entomologist's Monthly Magazine*. Incidentally Mr. Walker mentions that Dr. Wallace's residence in these islands, after a lapse of more than thirty years, is not forgotten, and that the Dutch translation of the "*Malay Archipelago*" is "as highly appreciated in the lands of which he gives so vivid a picture as the original work is at home."

AT the Physikalisch-Technische Reichsanstalt, Berlin, copies of standard mercury resistances are being constructed in which the mercury does not require renewal (*Wiedemann's Annalen*). They consist of U-shaped tubes filled with mercury in a vacuum and then sealed by fusion. Into each of the ends are fused three thin platinum wires connecting with the main current, the secondary circuit, and the galvanometer respectively. Since the connections are rigidly joined to the glass, it is possible to employ platinum wires as thin as 0.3 mm. so that there is no danger of heat being conducted into the mercury from without. The copy, mounted in a perforated brass box with an ebonite lid, is immersed in petroleum contained in another brass box, so that the binding screws are covered. This box is again surrounded during the experiment with a mixture of fine ice and water. The resistance is thus taken at a temperature which can easily be obtained, and which is uniform throughout the containing vessel.

AN apparatus for demonstrating the difference of potential at the poles of a galvanic cell has been constructed by Messrs. Elster and Geitel, of Wolfenbüttel (*Zeitschr. für Phys. und Chem. Unterricht*). It is a modification of Thomson's water dropping influence machine. Two insulated metallic vessels can be filled with water by pressing a rubber ball communicating with a three-necked jar. The jets enter the vessels through two metal rings. One of these rings is connected with the positive pole of the cell. The jet on passing through becomes negatively charged, and the charge is communicated to the vessel and through a wire to the second ring, which acts by induction on the other jet. A strong positive charge is soon accumulated on the outside of the second vessel, and can be exhibited by a gold leaf or aluminium foil electroscope.

IN 1869 it was decided, in France, to give a medal and pension of 250 francs to every old soldier of the Republic and the Empire who could show two years of service, or two campaigns, or a wound. An interesting statistical record of these "*médillés de Sainte-Hélène*" as of "*a generation which is disappearing*," is given by M. Turquan in the *Revue Scientifique*. The first list, in 1870, comprised 43,592 names, and these men

must have almost exclusively served under the Empire. They are now reduced to 27. The oldest, Vivien by name, a Lyons man, is now 106. When 13 he was with Bonaparte in Egypt, fought in 22 campaigns, and was one of the Imperial Guard at Waterloo. The youngest is 92, and served in the navy. The mean age of the 27 survivors is 97 or 98 years. The annual number of deaths in this body of men reached a maximum of 6456 in 1872, since which year it has been gradually diminishing. The proportional mortality rose, in general, till 1889, but in the years since there has been a marked fall, testifying to the exceptional vitality of those late survivors. M. Turquan calculates that this remnant will have wholly disappeared by the end of the century. Going back to 1815, he estimates the generation to which the men belong at about 300,000, with a mean age of 25 years, and that 500,000 births between 1785 and 1795 would concur to its formation. From figures relating to the Napoleonic wars he comes to the grim conclusion that one man in five of those born between the years just named was destined to die in war. It is, he says, to the immense losses of men during the ten years of war of the Empire that the present generations owe their low birth rate.

MR. J. R. S. CLIFFORD offers some interesting observations in the January number of *Nature Notes*—the Selborne Society's magazine—on the Death's head moth and bees. Last July a friend of his at Gravesend found one of these huge moths trying to gain access to a hive, having evidently been drawn to the spot by the odour of the honey. This disposes of doubts which have been suggested as to the old statements about this moth's habit of entering hives when it has a chance. The construction of modern hives keeps it out, but "where old style hives are used, the moth can and does enter, and occasionally one has been found dead within a hive, the bees, being unable to remove so bulky an insect, having taken the precaution to embalm its body with what is called *propolis*." According to Mr. Clifford, some Continental bee keepers have discovered that "the bees are aware they are liable to the intrusions of this big moth," and when the bees are "located in the old fashioned hive, the insects erect a kind of fortification at the portal. This is constructed with a narrow passage and a bend, past which the Death's head could not possibly make its way, and which it has no jaws to bite through."

We learn from the *Agricultural Journal*, issued by the Department of Agriculture at Cape Colony, that much attention is being given there to questions connected with the fruit export trade. The department is in correspondence with the steamship companies with a view to securing every possible encouragement to the trade, which is expected to be taken up on a considerable scale this year. Replying to inquiries on the subject, the Castle Mail Packets Company announce that they will give every publicity to the rates of freight to be charged and the stowage arrangements, &c. The Company will also concede a somewhat lower rate for the less remunerative fruits carried in the cool chambers, and will reserve a cool and well ventilated part of the vessel for conveyance of fruit as ordinary cargo. Careful instructions have been issued to captains of the Company's vessels in regard to the stowage and carriage of fruit.

DR. THEODOR MANWELL has issued a useful catalogue of Russian medical dissertations and other works he has collected and presented to the Royal College of Surgeons of England. In order that the dissertations may be of service to students who do not read Russian, he has indicated the nature of each work in English, and has given references to such abstracts in the *Lancet* or elsewhere as he has himself made or happens to be acquainted with.

AN excellent "Child Life Almanack" for 1893, by A. M. Clive Bayley, has been published by Messrs. G. Philip and Son. It is issued as an extra number of "Child Life," and the object, as the author explains, is to provide teachers with suggestions both for lessons to be prepared and observations to be made. Teachers who may wish to give "seasonable" lessons will find many most useful hints as to what really goes on in nature during the various periods of the year.

MR. JOHN BROWNING, optical and physical instrument maker, has issued an illustrated catalogue of magic, dissolving view, and optical lanterns, lime light apparatus, and slides.

THE extraordinary diversity in the temperature at which different micro organisms flourish and multiply, has from time to time been the subject of some interesting investigations by Fischer, Globig, and others. Thus Fischer isolated fourteen different species of bacteria from the sea water in Kiel harbour, and from soil in the town itself. These he was actually able to cultivate successfully at the freezing temperature ( $0^{\circ}\text{C}$ ) as well as at from  $15$  to  $20^{\circ}\text{C}$ . Globig, on the other hand, studied the behaviour of micro organisms at high temperatures and separated out no less than thirty varieties from garden soil which would grow at  $60^{\circ}\text{C}$ . Some of these were even able to develop at  $70^{\circ}\text{C}$ , whilst the majority refused to grow at all below  $50^{\circ}\text{C}$ , some still more fastidious individuals objected to any temperature below  $60^{\circ}\text{C}$ , and others again required a temperature of between  $54^{\circ}$  and  $68^{\circ}\text{C}$ . One bacillus, however, was discovered more catholic in its taste in this respect, for whilst growing at  $68^{\circ}\text{C}$  it managed to develop also at from  $15$  to  $20^{\circ}\text{C}$ . Some fresh contributions on the growth of micro organisms at low temperatures have recently been made by Forster of Amsterdam (*"Ueber die Entwicklung von Bakterien bei niedrigen Temperaturen"*). As far back as 1887 Forster described a phosphorescent bacillus obtained from sea-water which was found not only capable of growing, but of producing the phenomenon of phosphorescence at  $0^{\circ}\text{C}$ . In further researches made by this investigator in conjunction with Bleekrode, it is stated that, although not many different species were found by them to develop at  $0^{\circ}\text{C}$ , yet immense numbers of individual bacteria belonging to this category were detected in very various media. Thus one cubic centimetre of milk as sent into the market contained 1000 such micro-organisms, whilst in a single gram of garden soil as many as 140,000 were found. Large numbers of such bacteria were also present in sea water obtained from the North Sea, and they were also found on the surface of fresh water fish as well as in their alimentary tract. It is well known that to successfully preserve meat and other articles of food it is necessary to employ a much lower temperature than  $0^{\circ}\text{C}$ , and experience has further shown that this is best done when the atmosphere is deprived of all moisture, as is accomplished by the compression and subsequent expansion of the air in enclosed spaces. Haddocks imported from Norway and thus artificially frozen were examined by Forster for bacteria. These fish were first killed and then exposed to a temperature of from  $20$  to  $40^{\circ}$  below  $0^{\circ}\text{C}$  until they became perfectly hard and stiffly frozen, when they were removed to a cold chamber in which the temperature varied from  $8^{\circ}$  to  $15^{\circ}$  below  $0^{\circ}\text{C}$ . In spite of the extremely low temperature to which these fish had been subjected, on examining them when still hard frozen, a considerable number of bacteria were found in the abdominal cavity which had been opened when the fish was killed. It is obvious that during the interval which elapsed between the killing of the fish and their transference to the freezing chamber, bacteria must have been able to gain access, but had not had time to multiply to any considerable extent before the fish was frozen. Forster points out, what is sufficiently apparent, that the packing of samples of water in ice when sent from a distance

for bacteriological examination to prevent the multiplication of the micro organisms present, is really of very little if any use at all. Thus it was already shown several years ago by Percy Frankland that the bacteria in filtered Thames water were able to multiply extensively, even when preserved for some days in a refrigerator.

THE additions to the Zoological Society's Gardens during the past week include a Bittern (*Botaurus stellaris*), European, presented by Lord Ilchester, F.R.S., two Hamsters (*Cricetus frumentarius*), British, presented by Miss Pugh, two Alligators (*Alligators mississippiensis*), from Florida, presented by Master Williams, a Common Snipe (*Gallinago arctica*), British, purchased

### OUR ASTRONOMICAL COLUMN

COMET HOLMES (NOVEMBER 6, 1892) —The following is a continuation of Herr Berberich's ephemeris of this comet, the places being for Berlin, midnight —

		R.A.	Decl.	Log $r$	Log $\Delta$
		$^{\circ}$ $'$ $''$	$^{\circ}$ $'$ $''$		
Jan	5	18 50	33 47.9	0.4119	0.3400
	6	19 59	46.4		
	7	21 8	45.0		
	8	22 18	43.7		
	9	23 30	42.6	0.4143	0.3516

The comet is now near to and south following  $\beta$  Andromeda. Reports from various Observatories state that the comet is now very dim.

COMET BROOKS (NOVEMBER 20, 1892) —This comet is now travelling very quickly. The ephemeris for Berlin, midnight, is continued below —

		R.A.	Decl.	Log $r$	Log $\Delta$	Dr
		$^{\circ}$ $'$ $''$	$^{\circ}$ $'$ $''$			
Jan	5	18 29 40	+66 5.4	0.0805	9.8562	7.82
	6	19 0 49	13.6			
	7	19 31 22	65 59.2			
	8	20 0 22	24.6	0.0806	9.8651	7.49
	9	20 27 8	64 32.4			
	10	20 51 19	+63 26.0	0.0811	9.8781	7.01

The unit of brightness is taken as that at midnight on November 21.

The track of the comet lies near the pole of the ecliptic, in the constellation Draco.

THE SPECTRUM OF COMET HOLMES —The spectrum of the comet appears to have been continuous without any trace of bright bands. At South Kensington it appeared to have its brightest part near the chief carbon fluting ( $\lambda$  517), but there was nothing which could be described as a line or fluting. As might be expected, there was a brighter continuous spectrum from the nucleus. The same result was obtained by Mr. Campbell at the Lick Observatory, and by Prof. Keeler at the Allegheny Observatory. The latter observer remarks that the spectrum is just what we should expect if the comet shines entirely by reflected sunlight.

THE RECENT OPPOSITION OF MARS —In the December number of *Astronomy and Astro Physics*, Prof. W. H. Pickering summarizes the conclusions derived from the observations of Mars at Arequipa as follows: (1) That the polar caps are clearly distinct in appearance from the cloud formations, and are not to be confounded with them. (2) That clouds undoubtedly exist upon the planet, differing, however, in some respects from those upon the earth, chiefly as regards their density and whiteness. (3) There are two permanently dark regions upon the planet, which under favourable circumstances appear blue, and are presumably due to water. (4) Certain other portions of the surface of the planet are undoubtedly subject to gradual changes of colour, not to be explained by clouds. (5) Excepting the two very dark regions referred to above, all of the shaded regions upon the planet have at times a greenish tint. At other times they appear absolutely colourless. Clearly marked green regions are sometimes seen near the poles. (6) Numerous so-called canals exist upon the planet, substantially as drawn by Prof. Schiaparelli. Some of them are only a few miles in breadth. No striking instances of duplication have been seen at this opposition. (7) Through the shaded regions run certain curved

branching dark lines. They are too wide for rivers, but may indicate their courses. (8) Scattered over the surface of the planet, chiefly on the side opposite to the two seas, we have found a large number of minute black points. They occur almost without exception at the junctions of the canals with one another and with the shaded portions of the planet. They range from thirty to one hundred miles in diameter, and in some cases are smaller than the canals in which they are situated. Over forty of them have been discovered, and for convenience we have termed them lakes.

The heights of some of the clouds were found to be not less than twenty miles, and indirect observations have led to the conclusion that the density of the atmosphere of the planet is less than that at the surface of the earth, but probably not as much as ten times less.

Prof. Pickering is of opinion that the opposition of 1894 will be quite as valuable to observers as that of 1892, the distance being but little greater, while the planet will be much farther north, and there is less likelihood of the surface being so much obscured by clouds as during the recent opposition.

### GEOGRAPHICAL NOTES

AN interesting illustration of the rapid development of South Africa is given by the recent appointment of a magistrate to reside near Lake Ngami to protect the interests of white traders, and enforce the laws restricting the sale of liquor and ammunition to the natives.

THE January number of the *Geographical Journal*, the new form of the Proceedings of the Royal Geographical Society, contains a paper and map of some importance by Mr. A. P. Harper, descriptive of the central part of the Southern Alps of New Zealand. Government surveyors have been sent for several seasons to map out the glaciers, and an effort is being made by thoroughly exploring and mapping the region to make it the Switzerland of the southern hemisphere in the estimation of tourists, as it is already by virtue of its fine mountain systems.

AN important paper on the physical conditions of the waters of the English Channel is published by Mr. H. N. Dickson in the new number of the *Scottish Geographical Magazine*. He shows how the ebb and flow of the tides in the Channel is affected by the characteristic form of the main feature of the coast line, viz. bays with the western side running nearly from south to north, turning at a sharp angle, and lying open to the east. The circulation of the water and its temperature were found to be largely determined by these conditions.

MR. COLLES gave a successful lecture to young people in the hall of the University of London, on Friday last, covering the first half of his subject, "All the World Over, in a very interesting way. Anecdotes of personal adventure combined with exceptionally fine limelight views of scenery to give a vivid impression of the regions touched upon. The second and last juvenile lecture, under the authority of the Royal Geographical Society, will be given on Friday, January 6, at 4 p.m.

THE Royal Scottish Geographical Society announces a course of educational lectures in continuation of those delivered by Prof. J. Geikie and Dr. H. R. Mill last year. The new course will be on the Geographical Distribution of Animals, by Mr. J. Arthur Thomson, who is at present delivering the Thomson Lectures at Aberdeen. The Society has also provided two special lectures to young people, by Prof. C. G. Knott, on Life in Japan, and by Mr. Graham Kerr on his recent travels in South America.

WE understand that a book of travel in Madagascar and Africa, by Mrs. Colville, F.R.G.S., describing the observations of the authoress on a recent extensive tour, will shortly be published by Messrs. Blackwood.

MR. J. W. GREGORY, assistant in the Geological Department of the British Museum, has joined as naturalist the sporting expedition of Lieutenant Villiers and others, which is on the point of starting up the Juba. From Bardera, the head of navigation, the party will traverse unknown regions to Lake Rudolf, and from there attempt to cross in a north-easterly direction, through the Galla country and Somaliland to Berbera on the Gulf of Aden.

### THE INTERNATIONAL ZOOLOGICAL CONGRESS AT MOSCOW

THE International Zoological Congress held its second session in Moscow during the month of August last, and with most commendable zeal the committee, to whose care the editing and publishing of the memoirs read were committed, now publish the first part of the volume of its Proceedings. This part is printed in royal octavo size, and contains 350 pages, with several illustrations. All the memoirs are in French, thirteen out of the total thirty having been translated from, it is presumed, Russian. In the first section—that of questions concerning biology and systematic and faunistic zoology from a general standpoint—there are three papers. J de Kennel replies to the queries of Prof L Cosmovici: (1) On a definite arrangement of the animal kingdom in "Phyla", (2) is there a type "Vermes"? (3) on a uniform terminology of the secretory organs of worms. Ch Girard on some points of nomenclature. J de Bédriaga on introduced species, and on hybrids, reptilian and amphibian. In Section II—the same subjects from a special standpoint—there are twelve papers.—P N Boutchinsky, on the Black Sea fauna, refers to a report on invertebrates of the Bay of Sebastopol by Pérciaslavtzeva, who records 639 forms found. He describes three zones: (1) from the surface to a depth of 175 feet, (2) from 175 to 280 feet in depth, with a minimum temperature of 6–7° C, and (3) from 280 to 700 feet, with a slightly higher temperature than in the previous zone, 8–9° C. From a depth of 700 feet the water contains a quantity, more or less large, of sulphureted hydrogen, the quantity notably increasing with the depth. T J Van-Beneden gives a note on the living and extinct *Cetacea* of the same sea. Gr Kojevnikov gives an account of the fauna of the eastern Baltic basin on many recent explorations. Dr J de Bédriaga treats of European and circum-mediterranean vipers. C Grévy gives a paper on the geographical distribution of the Carnivores, and T Richard, one on the geographical distribution of the Cladocera crustacea. H de Jhéring makes some observations on insects' nests made of clay. Prof A Brandt gives a classification of animal variations according to their causation. Prof A Milne Edwards and E L Bouvier give a most interesting account of the varieties and distribution of *Parapagurus pilosimanus*, S T Smith a table with the comparative measurements of forty two specimens, is appended. *P. abyssorum* and *var scaber*, are reduced to the first named species. F Vejdosky describes *Thuricola gruberi*, n sp, and *Monodontophrya longissime*, gen et sp nov, the former from a stream near Bodenbach, the latter in the alimentary tract and body cavity of *Rhynchelmis lunocella*, Holm. In a short note Dr J de Bédriaga calls attention to some differences between *Chalcidus simonyi*, Steind, and *C. viridanus*, which forms Boulenger and Steindacher have proposed to unite, and thinks that *Molge luschanii*, Steind, neither belongs to *Molge* nor to *Salamander*, but to a European and American genus, not however named by him.

The third section contains eight papers on histology and embryology. N Kholodovski, contributions to a mesoderm and metamer theory. A Putzine, note on the formation of the germ of the peripheric nervous system. V Roudnev, note on the development of the cardiac endothelium in Amphibians. Mme O Tikhomirova, on the development of *Chrysopa perla*. Fr Vejdosky, on the segmentation of the ovum and the formation of the blastoderm in the Pseudoscorpiones, and on a rudimentary organ in the same. N Koulaguine, contribution towards the history of the parasitic hymenoptera. A Tikhomirov, value of embryological research for classification. Section IV, physiology.—C Khvorostiansky, on the luminosity of animals from the White Sea.

In Section V, devoted to morphology and comparative anatomy, L Cosmovici writes as to the purport of the "aquiferous system," "segmentary organs," "excretory organs," and "nephridia." H de Jhéring, on the presence or absence of an excretory apparatus in the genital organs of the metazoa. P Mitrophanov, note on the metameric significance of the cranial nerves. N Nassonov, on the position of the Strepsiptera in the animal system, according to the facts of post-embryonal development and of anatomy. A O Kovalevsky, on the excretory organs of the terrestrial Arthropods. N Zograf, on the origin and parentage of the Arthropods, more especially the tracheal bearing forms.

### A BOTANIST'S VACATION IN THE HAWAIIAN ISLANDS

THE new number of the *American Botanical Gazette* (vol xvii, No 12) contains the first part of a paper by Prof D H Campbell, describing his experiences during a vacation spent last summer in the Hawaiian Islands. We reprint the following passage—

On awakening upon the seventh day out, and looking through the port hole of my state-room, I saw that we were sailing near land. Rugged barren looking hills were seen, and, going upon deck, I learned that this was Oahu, the island upon which Honolulu is situated. As we skirted the shore at a distance, I soon spied a grove of unmistakable coconut palms, the first hint of the tropical vegetation to which I was soon to be introduced. Beyond was the bold promontory of Diamond Head, an extinct volcanic crater, forming a great bowl with rugged sides, right at the water's edge. Beyond this, and bounded partly by it, is the bay upon whose shores stands the city. Back of it rose abruptly a chain of mountains, in places about three thousand feet above sea level, and furrowed by deep valleys, whose walls, as well as the cloud capped summits of the hills, were covered with the most wonderfully verdant vegetation. Never before had I realized the possibilities of green. Blue greens, yellow greens, gray greens, and positive greens, with all degrees of these and others that are indescribable, combined to form what Whistler would term a symphony in green.

As if to vie with the colours of the mountains, the sea exhibited an equally wonderful variety of tints. Outside the harbour is a coral reef, and within this the water is of the pale green common to shallow ocean water, but outside it deepens very rapidly into the vivid blue of the open ocean. From a distance the line is clearly seen, but, as the observer approaches shore, the water changes from deep blue through every shade of blue and green until the pale green of the water within the harbour is reached.

As we approached land numbers of the queer outrigger canoes of the natives were met, and from the wharf boys jumped into the water and swam about the ship in the hope of persuading some of the passengers to throw over to them coins, which they were very skilful in diving for.

On the way to the hotel a few gardens were passed, and in them everything was strange. By far the most striking thing was the superb *Poinciana regia*. Although I had never seen this before I recognized it in an instant from a description of Charles Kingsley's, read long ago. Surely in the whole vegetable kingdom there is no more splendid plant. A spreading flat topped tree, perhaps thirty feet high, with feathery green, acacia like foliage and immense flat clusters of big flaming scarlet flowers that almost completely hide the leaves so that the tree looks like an immense bouquet. They were in their prime about the time of my arrival in Honolulu, and continued to flower more or less for the next six weeks. Pretty much everything in Honolulu, except the cocoanuts and an occasional haw tree (*Paritium tiliacum*) is planted, but people seem to vie with each other in seeing how many different kinds of plants they can grow, and the result is that the place is like one great botanical garden. To Dr Hillebrand this is said to be largely due, as he was one of the first to introduce foreign ornamental plants, and his place, which is kept much as it was at the time he left the islands, was a very remarkable collection of useful and ornamental plants from the warm regions of almost the whole globe.

Probably the first thing that strikes the traveller from the cooler regions is the great variety and number of palms. Of these the beautiful royal palm (*Oreodoxa regia*) is easily first. With its smooth columnar trunk, looking as if it had been turned, encircled with regular ring-shaped leaf-scars, and its crown of plummy green leaves, it well deserves its name. Other characteristic palms are various species of betel palms (*Areca*), wine palm (*Caryota*), sugar palm (*Arenga*), and a great variety of fan-palms of different genera. None is more beautiful than a thrifty young cocoa palm, but unfortunately it is very subject in the Hawaiian Islands to the ravages of some insect which eats the leaves and often renders them brown and unsightly. Indeed, it is almost impossible to find a specimen which is not more or less disfigured by this pest. The trunk of the cocoanut tree is usually more or less crooked, and in old specimens much too [all]

for its thickness, so that the old trees look top heavy. The date palm flourishes in Honolulu, where it is quite dry, but does not do so well in the wetter parts of the island.

On studying the other trees, one is struck at once by the great preponderance of Leguminosæ, especially Cæsalpinieæ and Mimoseæ. All about the town, and growing very rapidly, is the algaroba (*Prosopis juliflora*), a very graceful tree of rapid growth, with fine bipinnate leaves and sweetish yellow pods, which animals are very fond of and which are used extensively for fodder. Add to this that the tree now forms the principal supply of fuel for Honolulu and we can realize its full value. Other leguminous trees that are planted are the monkey pod (*Phacelolobum samang*), tamarind, various species of *Bauhinia* and *Cathartocarpus*. One species of the latter with great drooping bunches of golden yellow flowers and enormous cylindrical pods three or four feet long, rivals the Poinciana when in full flower.

Mingled with these are a great number of shrubs and trees with showy flowers or leaves, most of them more or less familiar to the stranger, either from pictures or from green-house specimens. Several species of *Musa* are grown, and when sheltered from the wind are most beautiful, but ordinarily the leaves are torn into rags by the wind. The tall and graceful *M. sapientum* has been largely supplanted by the much less beautiful Chinese banana, *M. Cavendishii*, which is short and stumpy in growth, but enormously prolific. The related traveller's tree (*Ravenia Madagascariensis*), is a common and striking feature of many Hawaiian gardens. Of the many showy flowering shrubs, the beautiful *Hibiscus Rosa-Sinensis* is one of the commonest, and is used extensively for hedges. One of the most striking hedges in the city, however, is the famous one at Puna Hou college, which is 500 feet long and composed of night-blooming cereus. I was not fortunate enough to see this when it was in full flower, but I saw a photograph of it when it was estimated that there were about 8000 flowers at one time.

Of the fruit trees ordinarily grown, the following may be mentioned. The mango is a very handsome tree with dense dark green foliage and masses of yellow and reddish fruit on long hanging stalks. The bread fruit tree is common, both cultivated and wild, and is a very beautiful tree of moderate size, with leaves looking like immense fig-leaves, and the fruit like a large orange. I saw no ripe fruit, and so had not an opportunity of testing its quality. Guavas of different varieties are extremely common, both wild and cultivated, and the various fruits of the whole citrus tribe grow well. The few specimens of temperate fruits were, for the most part, much inferior to those of the United States. Of the fruits that did not strike my fancy, at least at first, was the alligator pear (*Persea gratissima*), a big green or purple pear-shaped fruit with an immense single seed. The pulp is somewhat waxy in consistence and very oily. It is eaten as a salad, and very much relished by the islanders, but the taste is acquired. The curious papaya (*Carica papaya*) is another fruit which did not appeal to my palate. Its big orange fruit, not unlike a melon in appearance when cut open, has a peculiar "squashy" flavour that suggested it having been kept a day too long.

Many showy climbers are planted, some of which, like *Stephanotis*, *Thunbergia* and *Allamanda* are superb, but there is one that is particularly obnoxious in colour, *Bougainvillea*, whose magenta floral bracts are an offence to the eye, forming a cataract of raw colour. It looks, as some one observed, as if it had just come from a chemical bath.

As soon as one gets fairly away from the city, it is at once seen that all the luxuriant vegetation is strange. Along the seashore is a plain gradually rising into low hills, both almost destitute of trees, except here and there a few cocoa palms along the shore. Of the strictly littoral plants among the most conspicuous is the curious *Ipomæa pes capree*, with deeply two cleft leaves and purplish pink flowers. In the fertile lowlands near the sea are the principal cane and rice fields, which with taro are the staple crops. The rice is cultivated entirely by Chinese, near Honolulu; but on the sugar plantations the Japanese are largely employed. To see a Chinese laboriously transplanting little handfuls of rice into straight rows or ploughing in the mud and water with a primitive plough drawn by a queer Chinese buffalo are sights very foreign to an American eye. Sugar cane is eminently productive in the islands, and, hitherto, has proved the main source of revenue, but now the Hawaiians are bewailing the depression caused by the free admission of sugar from other countries into the United States; and, hitherto, their pro-

duct has enjoyed practically a monopoly of the American market, having been admitted by treaty free of duty.

I made several trips up the valleys back of the city, but owing to the almost constant rain in many of them, these were not always agreeable. However, one is richly repaid by the luxuriance and variety of the vegetation. For a mile or two we pass between grass-covered hills, or hills overgrown in places with the lantana, which, introduced as an ornamental plant, has become a great pest. This plant covers some of the hills with an absolutely impassable thicket, and spreads very rapidly, so that it is a serious problem what is to be done with it. Of the common roadside plants, an orange and yellow milkweed and the showy white *Argemone Mexicana* were the most conspicuous. As one proceeds farther, where more moisture prevails, the variety becomes larger. Thickets of *Canna* and a *Clerodendron* with double rosy-white flowers, are common, and the curious screw-pine (*Pantanus odoratissimus*) is occasionally seen. This latter is a very characteristic plant, but is much more abundant in some of the other islands. In this region some very showy species of *Ipomœa* are very common, among them the well known moon-flower, *I. bona nox*.

With the increase in moisture, as might be expected, the mosses and ferns increase in number and beauty. There are many of them of types quite different from those of the United States. One of the commonest ferns of the lower elevation in *Microlepia tenuifolia*, a very graceful fern with finely divided leaves and terminal sori. Species of *Vittaria*, with very long undivided leaves, are also common here.

As we ascend one of the commonest ferns is *Sadleria cyathoides*, a very large fern, often more or less arborescent. Ascending still higher the number and variety of ferns increases rapidly, and many beautiful and interesting ferns and mosses and liverworts become common.

At about one thousand feet elevation we begin to meet with species of *Cibotium*, to which genus belong the largest of the tree ferns of the islands. Here, also, I met for the first time with the smallest of all the ferns I have ever seen, *Trichomanes pusillum*. This dainty little fern, one of the *Hymenophyllaceæ*, forms dense mats on rocks and tree-trunks, looking like a delicate moss. The full grown frond is fan shaped, and, with its stalk, is not more than half an inch high. These tiny leaves, nevertheless, in many cases bore sporangia.

## SOCIETIES AND ACADEMIES

### LONDON.

Royal Society, December 8—"Preliminary Account of the Nephridia and Body Cavity of the Larva of *Palæmonetes varians*." By Edgar J. Allen, B.Sc., University College, London. Communicated by Prof. W. F. R. Weldon, F.R.S.

The Green Gland, in a larva of *Palæmonetes* which is a few days old, consists of an end sac, which communicates by means of a U-shaped tube with a very short ureter, opening at the base of the second antenna. At the time of hatching, the gland consists of a solid mass of cells, without a lumen. In later stages the tube of the gland enlarges to form the bladder. The enlarged bladders of the two sides subsequently meet and fuse in the middle dorsal line, forming the nephroperitoneal sac described by Weldon and Marchal.

The Shell Gland is found in late embryos and young larvae of *Palæmonetes*. It consists of a short renal tube, with a considerable lumen, which communicates internally with an end-sac, and opens externally at the base of the second maxilla.

Sections through the anterior region of the thorax of *Palæmonetes* show that the body cavity may be divided into four regions: a dorsal sac, surrounded by a definite epithelium, in which the cephalic aorta lies, but which does not itself contain blood; a central cavity, containing liver, intestine, and nerve cord; two lateral cavities, containing the proximal ends of the shell glands; and fourthly, the cavities of the limbs, which contain the distal ends of the same organs.

In late embryos of *Palæmonetes* solid masses of cells lie upon either side of the cephalic aorta. The dorsal sac is formed by the hollowing out of these masses of cells. Two lateral cavities are thus formed, which are separated by the aorta. The protoplasm of the cells lining these cavities, which is at first gathered into masses around the nuclei, then spreads out into a thin sheet, drawing away from the lower portion of the aorta, and causing the two lateral cavities to unite ventrally, and so form a single sac.

In the posterior region of the thorax the central and lateral cavities are similar to those of the anterior region, whilst dorsal to them the pericardial chamber lies. This chamber is separated from the central body cavity by the pericardial septum. The genital organs are situated immediately below the front end of this septum.

A comparison with the body cavity of *Peripatus* suggests the following relations. In the anterior region of the thorax of *Palamones* the dorsal sac is homologous with the dorsal portions of the mesoblastic somites of *Peripatus*, and its cavity is a true coelom. The central and lateral cavities, together with the cavities of the legs, represent the pseudocoel. In the posterior region of the thorax the cavities are all pseudocoelomic, and agree with those of the adult *Peripatus*.

December 15.—"Preliminary Note on the Relation of the Ungual Corium to the Periosteum of the Ungual Phalanx." By F. A. Dixey, M.A., M.D., Fellow of Wadham College, Oxford. Communicated by E. A. Schaffer, F.R.S.

Chemical Society, December 1.—Prof. A. Crum Brown, President, in the chair.—The following papers were read.—The isolation of two predicted hydrates of nitric acid, by S. U. Pickering. The author announces the isolation of two crystalline hydrates of nitric acid, the monohydrate and the trihydrate, melting at  $36.8^\circ$  and  $-18.2^\circ$  degrees respectively. In the case of either the melting-point is lowered by the addition of acid or water. The existence of these compounds was foreseen from an examination of the curves plotted from Bertholet and Thomsen's heat of dissolution values. This result is an important confirmation of the author's views.—Anhydrous oxalic acid, by W. W. Fisher. The best method of obtaining crystallized anhydrous oxalic acid is by allowing the hydrated acid to remain in contact with concentrated sulphuric acid for some months in a sealed glass tube. Oxalic acid is soluble in about 30 parts of cold sulphuric acid, the anhydrous acid dissolves with absorption of heat, whilst the reverse is the case with the hydrated acid. Anhydrous oxalic acid may be crystallized from nitric acid of sp. gr. 1.5. Oxalic acid may be completely dehydrated in a vacuum at  $60^\circ$ , the anhydrous acid is soluble in ethyl oxalate or glacial acetic acid, and separates from these solvents in a powdery form.—The production of orcinol and other condensation products from dehydracetic "acid," by N. Collie and W. S. Myers. The authors have obtained orcinol by the action of barium hydrate on dehydracetic "acid" or dimethylpyrone, on boiling a mixture of syrupy caustic soda and dehydracetic "acid," a true carboxylic acid is first produced, and, losing carbonic anhydride, yields orcinol. Among the products of the interaction of barium hydrate and diacetylacetone bright yellow needles melting at  $180-181^\circ$  are found; these probably consist of a naphthalene derivative  $C_{11}H_8O_2$ . Amidodehydracetic "acid," obtained in long needles melting at  $192-196^\circ$ , by the action of strong ammonium hydrate on dehydracetic "acid," readily yields dehydracetic "acid," on acid or alkaline hydrolysis.—Observations on the origin of colour and on fluorescence, by W. N. Hartley. It cannot be stated in general terms that colour is due to special methods of atomic arrangement; the statement may, however, be applied in a restricted sense to certain organic compounds, especially to those included in the class to which organic dye stuffs belong. It is pointed out that all open chain hydrocarbons exert a continuous absorption, the extent of which depends on the number of carbon atoms in the molecule. The condition of strain and instability existing in many coloured substances has been remarked by Armstrong; the author points out that all organic colouring matters are endothermic compounds, and considers this to be the physical cause of what Armstrong terms "reactivity" or "high potential." It is shown that anthracene is not colourless, but has a true greenish-yellow colour in addition to its fluorescence. A number of experiments on fluorescence are detailed, and the following conclusions drawn from them:—(1) Alcoholic solutions of quinine exhibit a beautiful, bright violet fluorescence. (2) Hydrochloric acid is not fluorescent. (3 and 4) Quinine hydrochloride and chloroform are feebly fluorescent, but without distinct colour. (5) Both hydrochloric acid and chloroform can extinguish those rays which are the cause of fluorescence in quinine. (6) Some alkaloids may be recognized by the degree and colour of their fluorescence. (7) Normal alcohols of the ethylic series and the fatty acids are fluorescent. (8) Glycerol has a violet fluorescence. (9) Benzene has a pale blue fluorescence, azobenzene a greenish-blue. (10) Rock crystal has a

pale bluish-violet fluorescence, flint glass a strong blue, and crown glass a very brilliant blue fluorescence. (11) Substances which are not fluorescent in strong solutions may become so on dilution, particularly if they exert a very powerful absorption of the ultra-violet or invisible spectrum.—The origin of colour, v. coloured hydrocarbons and fluorescence. A reply to Prof. Hartley's observations on the origin of colour and of fluorescence, by H. E. Armstrong. If attention be paid to vividly coloured organic substances, it is a most remarkable fact that in those cases in which the "constitution" is fairly well established coloured substances are found to be all of one type. The author starts from this basis to inquire whether all coloured organic substances are not similar in type. Hartley's remark that all organic colouring matters are endothermic compounds has little importance in the present connection, inasmuch as the converse does not hold. The author contends that before admitting the fluorescence of many substances, e.g. alcohol and its homologues, every precaution must be taken to ensure their purity, instances in which easy explanation of the fluorescence of certain substances is possible are given. Hartley's observation that anthracene is coloured strongly confirms the author's hypothesis. Anthracene is fluorescent, and may be represented by a quinonoid formula, whilst its isomeride phenanthrene, which cannot be so represented, is colourless and non fluorescent. Furthermore, whilst intense colour is produced by "weighting" what the author terms the "quinonoid radicals" of anthracene by replacing the central hydrogen atoms by a halogen, no such effect attends the similar treatment of phenanthrene, dibromophenanthrene being colourless like the hydrocarbon. And yet anthraquinone and phenanthraquinone are coloured yellow and deep orange respectively. Reference is made to other coloured hydrocarbons, viz. carotin and the red hydrocarbon,  $C_{25}H_{18}$ , recently investigated by Graebe. The formula assigned to the latter by Graebe—

—is an improbable one, such a substance would be colourless. The author gives a possible constitution, and, for the present, proposes to call the compound "erythrophene." The yellow hydrocarbon,  $C_{25}H_{18}$ , obtained together with this, is possibly a diphenylated anthracene, and may be termed "xanthophene." The "quinonoid radicals" in both hydrocarbons are heavily "weighted," hence their strong colour. With reference to Hartley's statement that a very little shifting of the region of absorption determines the presence or absence of colour in a compound, it is contended that this shifting may be due to a special character of structure. The author then explains his views as to the manner in which the "quinonoid mechanism" conditions colour. He suggests that in quinonoid compounds there are two "colour centres" corresponding to and expressed by the symbol  $\odot$  in formulae such as he has used in representing coloured substances. These centres co-operate in producing colour through interaction of the light waves which traverse them. Substances in which there are no such co-operating centres may absorb generally and selectively in "ultra" or "infra" regions of the spectrum, but without exhibiting "visible colour."—The origin of colour, vi. azobenzene, by H. E. Armstrong. Azobenzene, a highly coloured substance, is generally represented as  $Ph-N=N-Ph$ , a formula in discord with the author's hypothesis explained in the preceding paper. Moreover, the formula usually attributed to the colourless diazo-salts ( $Ph-N=N-Cl$ , for example) represent them as comparable in constitution with azobenzene. The behaviour of azobenzene towards bromine and other reagents leads the author to doubt the correctness of the conventional formula assigned to it, and to consider the following a more probable one:—

—The reduction products of dimethyldiacetylpentane, by F. S. Kipping. The author shows that dimethyldiacetylpentane, a diketone produced by the hydrolysis of ethyl dimethyldiacetylmalate is converted by reduction with sodium in a moist ethereal solution into dimethyldihydroxy-pentane and a compound

which, judging from the manner in which it is formed, may be regarded as tetramethyldihydroxyheptamethylene

—The products of the interaction of zinc chloride or sulphuric acid and camphor (third notice), by H. E. Armstrong and F. S. Kipping. The authors have previously shown that the crude product obtained on heating camphor with sulphuric acid or zinc chloride contains 1. 2. 4 acetylorthoxylene. On oxidizing the oil remaining after the separation of the latter substance, α-methylglutaric acid is formed. This acid being the characteristic oxidation product of the phorone obtained by distilling calcic camphorate, it is probable that a homologue of this phorone is present in the camphor product. —The Griess Sandmeyer interactions and Gattermann's modification thereof, by H. E. Armstrong and W. P. Wynne. In employing the Griess Sandmeyer methods for displacing the amido-group by halogens, the authors find that, in very many cases, much better results may be obtained by operating at relatively low temperatures instead of at the boiling point. It appears also that the Gattermann process affords a larger yield than the Sandmeyer process, only because it is carried out at a lower temperature. —Methods of observing the spectra of easily volatile metals and their salts, and of separating their spectra from those of the alkaline earths, by W. N. Hartley. Persistent flame colourations of easily volatile metals, such as lithium, potassium, rubidium, caesium, and thallium, may be obtained by heating beads of their fluosilicates, borates or silicates, on platinum wires in the Bunsen flame. If the substance to be spectroscopically examined be converted into a borate, the spectra of the alkali metals may be first observed, and on subsequently passing hydrogen chloride into the flame, the spectra of the alkaline earth metals may be rendered visible. —Manganese borate, its constitution and properties, by W. N. Hartley and H. Ramage. Manganese borate, after drying *in vacuo* over sulphuric acid has the composition  $\text{MnH}_2(\text{BO}_3)_2 \cdot \text{H}_2\text{O}$ . On heating at 100° it loses one molecule of water, and at a red heat two molecules more of water are lost, leaving a salt of the composition  $\text{Mn}(\text{BO}_3)_2$ . From the rate of loss of water with rise of temperature the existence of a number of intermediate salts is inferred. Manganese borate possesses a maximum of solubility in water at 18°, and a minimum at 80°. This is probably due to dehydration of the compound having the composition  $\text{MnH}_2(\text{BO}_3)_2 \cdot \text{H}_2\text{O}$ .

Anthropological Institute, December 13.—Edward B. Tylor, President, in the chair.—Mr. Arthur J. Evans read a paper on the prehistoric interments of the Bahi Roca caves near Mentone and their relation to the Neolithic cave burials of the Finale. He described the recent discovery of three skeletons in the cave of Barmas Grande, and showed that the character of the sepulchral rites practised, the relics found, and the racial type of the human remains agreed with the earlier discoveries made by M. Rivière and others in the same caves. Mr. Evans, however, opposed the theories that had been put forward as to the Palaeolithic date of "Mentone Man." The bones of extinct Pleistocene animals and implements of the Mouster and Magdalenian types found in the cave earth above the interments proved nothing, for the simple reason that they were interments. No remains of extinct animals had been found in actual juxtaposition with the skeletons. On the other hand the complete absence of pottery, of polished implements, and of bones of domesticated animals in this whole group of interments and the great depth at which they occurred proved that the remains belonged to a very early period. Evidence was here supplied of an earlier Neolithic age than any yet authenticated. Still the remains belonged to the Later Stone Age and to the days of a recent fauna. Mr. Evans compared some bone ornaments found with the so called hammer-heads of the chambered barrows of Scandinavia and the decorative system with that found on Neolithic pottery in northern Europe. He further showed that interments of the same tall dolichocephalic race in a more advanced stage of Neolithic culture were to be found in the cave-burials of the Finale district further up the Ligurian Coast. The physical form and the character of the sepulchral rites was essentially the same. Only the skeletons were here associated with polished axes, pottery, and bones of domesticated animals. The direction from which the new civilizing influences had come was indicated by imported shell

ornaments from the southern and eastern Mediterranean, in the Mentone caves the imported shells were from the Atlantic. In conclusion Mr. Evans showed that the latter Finale interments exhibited forms of pottery and implements identical with those of the Italian terremare of the other side of the Apennines, and included ceramic shapes which seemed to be the prototypes of vessels found in the early Sikel tombs of Mycenaean age. The Italic culture here revealed fitted on not only to that of the early pile-settlements of the Po Valley and the Lake dwellings of Switzerland, but might be traced to the Danube valley, to Thrace, and the Troad. Amongst other parallel forms owl-like idols bearing a strong resemblance to those described by Dr. Schliemann from the site of Troy had been found by Padre Morelli of Genoa in one of the Finale caves.—Dr. H. Colley March read a paper in which he sought to prove that the peculiar features of Polynesian ornament are due to a mythology which is, in the main, a symbolism of origin and descent. Thus regarded, unattractive and bewildering designs are resolved into emblems of divinity and demonstrations of lineage. He traced the evolution and defined the attributes of Tiki, explained the nature of oromatus and the meaning of unuu, described the various methods of recording pedigrees, whether along a male or along a female line, and illustrated the mythical use of tapa and sinnet. He discussed, as modes of origin, totemism, gemination, and generation, of which Polynesian examples were given, tabulated the kinship of the superior gods, set forth in full the Tane cult, especially in relation to the axe and the drum, and endeavoured, in conclusion, to account for the development of the complicated Mangian adze.

#### EDINBURGH

Royal Society, December 5.—Sir Douglas MacLagan, President, in the chair.—After an introductory address by the President, a note by Prof. Cayley, on uniform convergence of series, was read.—Prof. Tait communicated a note by Prof. P. H. Schoute, of Groningen, on the locus of a uniformly revolving line, which always passes through a point moving uniformly round a circle, and which always lies in a normal plane passing through the centre of that circle. The degree of the locus is found by an elegant and very simple method.—Dr. C. Hunter Stewart gave notice of a paper on the further development of Kjeldahl's method of organic analysis. The carbon, as well as the nitrogen, present can be determined by the same analysis in the developed method, and much smaller quantities than formerly of the substance analyzed lead to results as accurate as those previously obtained.—Prof. Tait read a note on the division of space into cubes. He gives a different, and more direct and short, solution by quaternions than that given by him some years ago.

#### PARIS

Academy of Sciences, December 26.—M. d'Abbadie in the chair.—Thermal elevation under the influence of injections of soluble microbial products, by MM. Bouchard and Charrin. An elevation of temperature recalling that observed by Koch is produced in a marked degree in tuberculous patients by injections of the toxic substances secreted by the pyogenic bacillus.—Vessels and clasmocytes of the hyaloid in the frog, by M. Ranvier.—Observations of Holmes's comet (November 6, 1892) made with the great equatorial of the Bordeaux Observatory, by MM. G. Rayet and L. Picart, report by M. Rayet.—Observations of Swift's comet (1892, I) made with the great equatorial of the Bordeaux Observatory, by MM. G. Rayet, L. Picart and F. Courty, report by M. Rayet.—On the laws of dilatation of fluids at constant volume, coefficients of pressure, by M. E. H. Aynagat.—Observations of Holmes's comet, made with the equatorial coude (32 cm) of the Lyon Observatory, by M. G. Le Cadet.—New experimental researches on the personal equation in transit observations, by M. P. Stroobant.—On conjugate systems and couples of applicable surfaces, by M. A. Petot.—On infinitesimal deformation and Bianchi's associated surfaces, by M. E. Cosserat.—On contiguous surfaces relative to the hypergeometrical series with two variables, by M. Levassieur.—Test for the convergence of series, by M. A. de Saint-Germain.—Criterion of divisibility by any number, by M. Fontès.—On the motion of a particle in the case of a resistance proportional to the velocity, by M. Elliott.—General form of the law of vibratory motion in an isotropic medium, by M. E. Mercadier.—Employment of springs in the measurement of explosive pressures. If errors due to the inertia of the moving parts of the indicator are to be avoided, the amplitude of the

tracing point must not exceed 1 mm in the case of pressures used in modern firearms. This necessitates careful reading with a microscope.—On the decrease of temperature of the air with the elevation, by M. Alfred Angot. Experiments conducted on the Eiffel Tower indicate a decrease for each 100 m., between the soil and a height of 160 m. ranging from 0.6° in December to 1.46° in June. Between 160 m. and 302 m. the decrease per 100 m. ranges from 0.64° in February to 0.96° in October. At 300 m. the decrease per 100 m. is on the average 0.5° in winter, 0.6° in autumn, 0.7° in spring, and 0.8° in summer.—On the temperature of the electric arc, by M. J. Violle. From calorimetric measurements made with a portion of the arc light carbon detached from the hottest part during the passage of the current, the temperature of the arc, *i.e.* that of the volatilization of carbon, appears as 3500°, assuming the carbon to have its theoretical specific heat, 0.52, at the higher temperatures. This temperature of volatilization is constant, whatever the power employed.—Remarks on high temperatures and the vaporization of carbon, by M. Berthelot. The vapour tension of carbon is quite appreciable even below volatilization, which involves the reduction of a polymer to the monomolecular state, thus in reality representing a chemical process. Higher temperatures than that of the arc can be attained by purely chemical means, such as the explosive combustion of a mixture of oxygen and cyanogen.—On the equality of velocities of propagation of electric waves in air and along conducting fibres, verified by the example of a large metallic surface, by MM. Ed. Sarasin and L. de la Rive.—On nets of electric conductors; reciprocal properties of two branches, by M. Vaschy.—On the enfeeblement of electromagnetic oscillations with their propagation and their subsidence, by M. A. Perot.—Determination of the coefficients of self induction by means of electrical oscillations, by M. P. Janet.—Doppler-Fizeau's method, exact and approximate formulæ, evaluation of the error involved, by H. de la Fresnaye.—Magnetic properties of oxygen at different temperatures, by M. P. Curie. A series of measurements with oxygen compressed to 5 and to 18 atmospheres respectively gave identical results at temperatures between 20° and 450°. Within this range, the volume coefficient of specific magnetization of oxygen varied inversely as the absolute temperature. The volume coefficient of magnetization of air at the ordinary pressure and at temperature *t* is given by  $10^6 k_t = 2760 \times T^{-1}$ , where *T* is the absolute temperature.—On the rotatory power of quartz at low temperatures by MM. Ch. Serret and C. E. Guye.—On the fusion of carbonate of lime, by M. A. Joannis.—Ammoniacal compounds derived from ruthenium sesquichloride, by M. A. Joly.—On an iodo-sulphide of phosphorus, by M. L. Ouyard.—Action of bismuth on hydrochloric acid, by MM. A. Ditté and R. Metzner.—Action of potash and soda on the oxide of antimony, by M. H. Cormilleux.—Relation between the heats of formation and the temperatures of the point of reaction, by M. Maurice Prud'homme.—On the study of the chemical reactions in a liquid mass by the index of refraction, by M. C. Féry.—On a propylamidophenol and its acetyl derivatives, by M. P. Cazeneuve.—Quantitative determination of impurities in the methylenes, by M. Er. Barillot.—Separation of micro organisms by centrifugal force, by M. R. Léze.—Loss of nitrogen in manures, by MM. A. Müntz and A. Ch. Girard.—Fermentation of manure, by M. A. Hébert.—Drying up of marshes in Russia, by M. Venokoff.—Chemical conditions of the action of ferments, by M. J. Effront.—On trichophytia in man, by M. R. Sabouraud.—Evolution of the functions of the stomach, by M. J. Winter.—On the histology of the organs attached to the male apparatus in *Periphriza orientalis*, by M. P. Blatter.—On the presence of a fossil Araliacea and Pteridiferiaceae in the coarse Parisian limestone, by M. Ed. Bureau.—On a new geological map of the French and Spanish Pyrenees, by MM. Emm. de Margerie and Fr. Schrader.—Differential motion of the ocean and the atmosphere; water tides and air tides, by M. F. de Saintignon.—On the perforation of the basaltic rocks of the Gulf of Aden by shingle; formation of a Giant's Kettle, by M. Jousseaume.

## AMERICAN MECHANISM

*Modern Mechanism* Edited by Park Benjamin, LL B., Ph D (London and New York Macmillan and Co., 1892)

IN order to appreciate this volume thoroughly, it is necessary in the first instance to consider the reason of its existence. Appleton's "Dictionary of Engineering," an American book, was published in the year 1851, and was the first to gather in cyclopedic form descriptions of products of American mechanical industry. Some thirty years afterwards it became necessary to bring the work up to date, and its complete reconstruction was decided upon. The editor observes that no previous work of a technical character had so signally, and so quickly, demonstrated its own usefulness, it rapidly became a recognized standard of American mechanical practice. Owing, however, to the great progress made in mechanical invention, and the marvellous rapidity with which electrical science has advanced, a new record of the results has become necessary, and hence the present volume.

The list of contributors includes the names of eminent men, well known in this country for their high attainments in the different branches of mechanical and electrical engineering, forming a sure guarantee that the information to be gleaned from the pages is valuable and accurate. It would be impossible in the space at our disposal to notice more than a small part of the contents. Some interesting information is to be found on the subject of aerial navigation, more particularly the interesting experiments being carried out by Mr Hiram S Maxim. Commenting on Prof Langley's statement, that with a flying machine the greater the speed the less would be the power required, Mr Maxim says: "In navigating the air we may reason as follows: if we make no allowance for skin friction and the resistance of the wires and framework passing through the air—these factors being very small indeed at moderate speeds as compared to the resistance offered by the aeroplane—we may assume that with a plane set at an angle of 1 in 10, and with the whole apparatus weighing 4000 pounds, the push of the screw would have to be 400 pounds. Suppose, now, that the speed should be 30 miles an hour, the energy required from the engine in useful effect on the machine would be 32 horse-power (30 miles = 2640 feet per minute,  $\frac{2640 \times 400}{33,000} = 32$ ). Adding 20

per cent for slip of screw, it would be 38.4 horse-power. Suppose, now, that we should increase the speed of the machine to 60 miles an hour, we could reduce the angle of the plane to 1 in 40, instead of 1 in 10, because the lifting power of a plane has been found to increase in proportion to the square of its velocity. A plane travelling through the air at the rate of 60 miles an hour, placed at an angle of 1 in 40, will lift the same as when placed at 1 in 10, and travelling at half this speed. The push of the screw would therefore have to be only 100 pounds, and it would require 16 horse-power in useful effect to drive the plane. Adding 10 per cent for the slip of the screw, instead of 20, as for the lower speed, would

increase the engine power required to 17.6 horse-power. These figures, of course, make no allowance for any loss by atmospheric friction. Suppose 10 per cent to be consumed in atmospheric resistance when the complete machine was moving 30 miles an hour, it would then require 42.2 horse-power to drive it. Therefore at 30 miles an hour only 38.4 horse-power would be consumed by atmospheric friction, while with a speed of 60 miles an hour the engine power required to overcome this resistance would increase eightfold, or 307 horse-power, which, added to 17.6, would make 481 horse-power for 60 miles an hour."

Mr Maxim goes on to observe that his experiments show that as much as 133 pounds can be carried with the expenditure of 1 horse-power, and under certain conditions as much as 250 pounds. It will be evident, therefore, that the question of motors is all important, and that the total weight per horse-power developed must be as low as possible. It is stated that the greatest force can be obtained from a compound high-pressure steam engine using steam at 200 to 350 pounds pressure, and such engines have been constructed weighing 300 pounds, the horse-power of these engines is not stated.

It will be interesting to watch the outcome of these investigations. They indicate that much information is being accumulated, and that sooner or later a successful aerial machine will be forthcoming.

The question of armour plates has long vexed the soul of the British Admiralty, many very costly trials have been carried out in order to find the most suitable plate for the service. All these data have probably been known in the States, and that country must have benefited by them. Under this heading we find much information in the book, American experiments being quoted and illustrated. Naturally, the Americans wish to make their own plates, and wisely endeavour to do so by rolling only, to do without the heavy expense of forging. These experiments show that the high-carbon nickel Harvey plate is undoubtedly the best plate ever tested. As a result of these trials, orders have been placed for plates for the cruisers under construction. An excellent full-page engraving is given of the U.S. armoured battle ship *Indiana*, and to judge by the blackness of the smoke she is not using Welsh coal! The article on steam boilers is well written, and very complete, containing much useful information. Among the many types of boilers illustrated there is a good print of the Yarrow torpedo boat boiler. We miss however, the familiar Thornycroft boiler, and note an American water tube-boiler for fast launches very like the Thornycroft in the arrangement of the tubes.

The boilers for marine purposes are purely of the British type, and there is nothing of importance to note on this subject beyond the many experimental results recorded.

Further on in the book there is an interesting description of railway-car heating. We are told that car-heating, in the usual acceptance of the term, has come to mean the heating of railway cars by the use of steam from the locomotive. This is important, showing as it does the direction in which American railway companies are moving in the solution of a problem at present occupying the best attention of engineers in this country. Gener-

ally, we are told, the systems consist of a separate hot-water circulating system in each car, in connection with a heater, fed by steam from the locomotive, by a continuous train pipe running the length of the train, and coupled together between the cars by flexible hose-pipes and universal couplings; the Sewall steam coupler being generally used. Another important railway necessity is the continuous brake. Under this heading the latest form of Westinghouse quick-action automatic brake is described. In the original design the brake is applied by the engine-driver allowing a little air to escape from the train pipe, lowering the pressure, and thus applying the brake by the automatic action of the triple valves. It is evident that the vehicle next the engine will feel this reduction first, and its triple valve will work before that on the second vehicle, and so on. On trains of ordinary length this very slight difference in time between the brake's application on each vehicle is of little consequence, but when this automatic brake is fitted to a long goods train it becomes a serious matter. The length of a goods train of fifty American cars is 1900 feet, and the brake should act instantaneously to be perfect. The new triple valve is itself designed to discharge air from the train pipe, so on the driver opening the driver's valve, allowing air to escape to apply the brakes, the reduction of pressure operates the triple valve on the first car; this lets out more air, and so on through the train, the brake on the last car, 1900 feet away, being operated in 2.5 seconds after that on the first car.

The vacuum automatic brake is not described or illustrated. This brake is now being more and more brought into use, and for general purposes it appears to be simpler and less liable to get out of order than its competitors.

A considerable part of the volume is taken up with the applications of electricity, for lighting and motive power purposes generally. On dynamo electric machinery much has been written and well illustrated. The reader is taken step by step from the rudiments of the subject to its latest applications, from a description of armatures to the arrangements of the field-magnets, then to the varying designs of dynamos, including most of the known machines. The same may be said on the treatment of the electric motors. Under the head of the transmission of power there is more useful information to be found, this being all the more interesting, because of the proposed use of electricity as a means of transmitting some of the power of Niagara to distant towns. There is, however, something wanting under the heading of electrical measuring instruments. The only ones mentioned are Weston's volt and ammeters. At the present time the street tramways of this country are in an uncertain stage as far as motive power is concerned; horse-power is admittedly expensive, the steam locomotive seems to have got into disrepute, the cable and electric traction appear to be struggling for the mastery. It is interesting therefore to read the memoir on electric traction in this volume. The accumulator system is just described, but the overhead cable or trolley system takes up the greater part of the space, so it is safe to assume that the latter is more generally in use, the principle of which is as follows. The current starts from the positive brush of the dynamo, passing out to the main conductor, suspended over the middle of the track, and along this conductor

until it reaches the point where the trolley of one of the motor cars is in contact. Here it divides, and a portion passes down through the trolley to the motors, and thence to the rails forming a return lead to the negative brush of the generator. The main portion of the current passes on to feed other cars upon the line in the same manner, each car taking the quantity of current necessary to develop the required power. There are at the present time nearly 500 electric railways in America, and taking the results of twenty-two electric trolley lines, we find that the expenses vary per car mile from 22.99 cents to 7.89 cents, the highest and lowest respectively. A view is given of the electric street railway at Washington, D.C., the overhead conductors being not at all unsightly.

On electric welding there is also much information, the Thomson process being very fully described. It consists briefly in completing the electrical circuit through the parts to be welded together, the resistance being sufficient to heat the parts so as to weld them, this being assisted by pressure.

The Bernado process is not described, in this process the work to be welded is connected to one terminal of the dynamo. The positive terminal being connected with a carbon rod, held in a portable insulated holder, the carbon rod is then placed on the work, and immediately withdrawn slightly, thus forming an arc, where the metal melts, and with skill much can be done.

The locomotive practice in America has long been of interest to locomotive engineers in this country, owing to the many differences in design and practice. A very good *résumé* of American practice is to be found in the memoir under this heading. A useful table is given showing a few leading dimensions, weights, &c., of typical engines in use. Take, for instance, the express passenger engine, a four-coupled bogie engine, the cylinders being 20 inches in diameter and 24 inches stroke. The driving or coupled wheels are 72 to 78 inches in diameter. The weight on coupled wheels is 75,000 pounds (33.48 tons), the total weight of the engine being 116,000 pounds (51.78 tons), and that of the tender 72,000 pounds (32.14 tons). Comparing these data, we find that the American engine is heavier than an 18x26 cylinder British engine and not so powerful, assuming equal steam pressures, the tender is light in a similar comparison, probably carrying less water. The reputed weight of trains hauled given in the table is of little use, because the speeds are not given, and for this reason comparisons cannot be made.

The paragraph on locomotive boiler construction is far too short, many interesting details might have been added. It is stated that the circular smoke-box tube plate is a conspicuous difference between the practices of the two countries, being purely American, whereas the Midland Railway Company have, amongst others, used the arrangement for some time. Owing to the enforced use of anthracite coal in certain parts, many peculiar designs of locomotive boilers have been used, the Wootton boiler being probably the most common. All, however, have particularly large grate areas, which, in the case of the Wootton, may in some cases exceed 76 square feet, or four times the area of the grate of

recent British engines. An illustration is given of an engine of this type, as well as a full-page engraving of a compound locomotive with a similar boiler. This compound is very different from the Webb or Worsdell engines common in this country, being the design of the superintendent of the Baldwin Locomotive Works. The cylinders are outside the frames—there are two on each side, viz one high-pressure and one low-pressure. The distribution of the steam being effected in each pair by one piston valve, each pair of pistons is connected to one crosshead, coupled in the usual way to the wheels.

A compound engine of the "Webb" type is also illustrated. This engine was constructed to Mr Webb's designs in this country for the Pennsylvania Railway in 1889. It is stated that the results of experiments showed a saving of fuel over the ordinary engine of from 20 to 25 per cent.

This book is so full of interesting matter of so varied a nature that it would be possible to prolong this notice far beyond the space available. Take, for instance, agricultural machinery, the Price ploughing outfit is typical of the rest, consisting of a traction engine drawing four gangs of three ploughs, the twelve ploughs cutting eleven feet wide. The subject of milling tools is also of interest, because it is only during the last few years British engineers have used this means of shaping metals, the system having been brought into general use in the States.

Under the head of the manufacture of steel all the usual processes are described. We are informed that the Whitworth compression process is only partly successful in the formation of sound ingots; with this statement we cannot agree, the Whitworth steel ingot after compression is certainly sound throughout.

Taking into consideration the great mass of information contained in the 900 odd pages of this work, and the general excellence of the matter accumulated, it is only just to congratulate the editor on the completion of a work which must prove useful to many, and which should find a place in all technical libraries. The volume goes far to describe modern American mechanism, exhibiting the latest progress in machines, motors, and the transmission of power.

### SEEDLINGS.

*A Contribution to our Knowledge of Seedlings.* By the Right Hon Sir John Lubbock, Bart, M P, F R S, D C L, LL.D., with 684 figures in text. In two volumes. (London, Kegan Paul, Trench, Trubner and Co, Ltd., 1892.)

SEEDS and seedlings have occupied the attention of Sir John Lubbock for a somewhat lengthened period. They have formed the subject of various communications, on his part, to the Journal of the Linnean Society and other publications. In the present volumes, modestly styled a "contribution," he gives us the details upon which his inferences have been founded.

The physical and chemical aspects of germination are entirely passed over, but the morphological phenomena are treated with a fulness never before attempted. The author has availed himself of the resources put at his disposal by the authorities at Kew, where the larger propor-

tion of the seedlings described were grown expressly for the purpose. The Natural History Museum and the Cambridge Botanic Gardens have also been requisitioned, and much help has been rendered by capable assistants, whilst the services of Sir Joseph Hooker and Mr Rendle, in looking over the proof sheets, are duly acknowledged. A work of such dimensions, crowded with detail, could hardly have been produced without such zealous co-operation. Nevertheless unity of plan and uniformity of treatment are conspicuous throughout, and thus comparison is readily effected.

Some previously published papers in the Journal of the Linnean Society, dealing with the causes which determine the form of leaves and cotyledons, are reprinted as the introduction to the treatise. The conclusion therein arrived at is that the form of the embryo, and especially that of the cotyledons, is essentially influenced by the form of the seed. On p 78 the author begins the detailed examination of seedlings taken from almost all the orders of flowering plants. Five hundred and thirty succeeding pages in the first volume, and five hundred and eighty-eight in the second volume, are thus occupied. This little bit of statistics will serve to show the amount of detail which is contained within these volumes. The plan adopted is to give, first of all, a general sketch of the principal modifications exhibited by the fruit and seed in each order. Then follows a more detailed description of the seed and of the seedling plant in various representatives of the order. As these descriptions are identical in plan throughout, they are of great value to the student of comparative morphology. Naturally some orders are much better represented than others, but sometimes the omissions are rather unfortunate. In the genus *Araucaria*, for instance, seedling representatives of which are common in botanic gardens and nurseries, the diversities in the form of the seedling and in the mode of germination are very remarkable. "Characters" derived from the seedling plant have been recognized as of the highest importance for classificatory purposes since the time of John Ray (1682-1703).<sup>1</sup>

But whilst this is generally the case, such extraordinary exceptions as that mentioned in *Araucaria* are very noteworthy, and not less so because the genus in question is one of the very oldest of which fossil botanists have cognizance.

Myrtaceæ and Sapindaceæ are remarkable for the extremely diverse character of the embryo in different genera, and of which due note is taken in Sir John Lubbock's book. In Rosaceæ, on the other hand, the diversity is much less, nor is there any important morphological difference in the seedlings of the great order Compositæ, and scarcely more in Umbellifereæ, so far as they are known. These are facts of great significance with reference to the theories of inheritance and relative antiquity of groups.

<sup>1</sup> It may not be without interest to cite what Ray says on this matter—*"Floriferæ dividimus in dicotyledones quarum semina nata bina foliis anomalis, seminibus dictis, quæ cotyledonum unum prætant, e terra erant vel in bina saltem lobos dividuntur, quamvis eo supra terram foliorum speciem non afferant, et monocotyledones quæ nec folia seminibus bina efferant nec lobos binos conduunt."* Thus Ray not only recognized the presence of one or of two cotyledons, but also their nature and their epigeal or hypogeal condition. As Ray has been mentioned, it is certainly not inappropriate to allude to Grew also, for the first chapter of his *"Anatomy of Plants"* (1682), and the whole of the fourth book is devoted to the seeds and seedlings and in perusing them the reader will perceive that Sir John Lubbock has in a few cases been anticipated by his celebrated predecessor.

The gradual evolution of the perfect plant from the seedling is indeed a subject of great interest to the phylogenetist, although it is difficult—nay, impossible—to separate those appearances which are merely hereditary from those which are the result of varying outward conditions, the more so because analogous conditions must have influenced the ancestors in past times even as they affect their successors now.

Amid such a mass of detail it is difficult to pick out points worthy of special note. We select two only out of many scores that might be mentioned. Some *Onagrad*s are remarkable for the intercalary growth which takes place in the cotyledons, of which several illustrations are given in Sir John Lubbock's book. They call to mind the experiments of the late Prof Dickie, who, by suppressing the plumule of seedling castor-oil plants, succeeded in inducing the cotyledons to continue their growth and to assume dimensions much greater than that which is habitual to them.

The small tubercles on the root of *Myrica californica* (vol. ii p. 523, Fig. 663) have, so far as we know, not previously been observed. The author compares them to those found on *Alnus cordifolia*, and it would be interesting to ascertain whether these outgrowths are caused by an organism analogous to *Schinzia alni*, as described by Woronin, or to that which induces the peculiar tubercles on the roots of Leguminosæ, recently studied by Prof Marshall Ward.

Monocotyledons generally have been rather badly treated by the author, although such genera as *Potamogeton*, *Aponogeton*, *Orontium*, and other Aroids, and Palms (of which not a single illustration is given) would have furnished examples at once interesting and easily accessible.

The work includes nearly seven hundred illustrations, faithfully executed, and very valuable to the student. The bibliography, in spite of its occupying no fewer than thirty-eight pages, is the weak part of the book. Some of the most important references are omitted, and whole series of species whose mode of germination has been recorded and some times figured, have been passed over. This only shows how colossal has been the task which Sir John Lubbock has set himself. We do not think the worse of the sun for having a few spots on his disc, nor are botanists at all likely to disparage this work because further research might have added a few more illustrations. As it is, it forms one of the most substantial and important contributions to botanical literature that have ever emanated from the press. It must continue to be a standard book of reference for generations, and it will, we hope, stimulate observers, according to their several opportunities, to prepare similar monographs on the various organs of plants.

MAXWELL T. MASTERS

### EPIDEMIC INFLUENZA

*Epidemic Influenza: a Study in Comparative Statistics.*  
By F. A. Dixey, M.A., M.D. (London: Henry Frowde and H. K. Lewis, 1892.)

**A**FTER an epidemic disease has visited a country, when the pathologist and practical physician have had their say, there still remains the work of the statistician to be done. It is his province to sum up the results

of the visitation in the clear light of hard figures, and to trace its onset and decline in mathematical curves. Such work is of value in more than one direction. It preserves for future generations a definite record of an epidemic of greater precision than the impression left on the mind of the physician. It enables a comparison to be drawn between our own experience and that of other countries by the sifting and sorting of facts which it necessitates. It may lead to the discovery of relationships with allied diseases which may prove of no small value to the pathologist.

This work has been done for influenza by Dr Dixey in a very thorough and painstaking manner from the material collected under the supervision of the Registrar-General. It says much for the completeness of our registration system in London, that it is possible to compile from them such tables and curves as those with which we are presented in this work, nor are such materials available from any other city in Europe. The only cities whose statistics have been found by Dr. Dixey sufficiently accurate for comparison with our own are Paris and Berlin.

Dealing first with the epidemic of 1889-90, he shows in Table 1 the rise and progress of the disease in London, as indicated by the weekly returns of fatal cases, grouped according to the seven age periods adopted in the official returns. Table 2 gives us, so far as the returns of the period permit, the similar figures for the epidemic of 1847-48. The similar characters of the two epidemics are strikingly illustrated: in both we see the same extreme suddenness of rise, and the same features of decline, rapid at first, but becoming gradually slower during the succeeding months. In the next two tables are included similar figures for Paris and Berlin, and in these, and in Table 5, the author gives an analysis of the meteorological conditions accompanying the rise and fall of the epidemic in the three cities. These are of interest as showing how little influence the weather had on the course of the disease as a whole.

In the tables which follow—which are perhaps of greater interest than any of the others Dr Dixey has compiled—the effects which influenza has exerted on the mortality from other diseases in London and other cities are shown. These effects are of two kinds: influenza may aggravate the mortality of pre-existent disease such as phthisis or heart disease, or diseases such as bronchitis or pneumonia may occur as complications of influenza and swell its death-roll. It is interesting to observe that whereas in 1847-48, which was in all respects a more fatal epidemic than that through which we have just passed, bronchitis showed the most extreme departure from the normal mortality, pneumonia holds that place in the late epidemic, while bronchitis falls into the second rank. In this connection may be mentioned a point of much interest illustrated in Tables 10, 11, and 12, which deal with the age incidence of influenza and its concomitant diseases. It is possible to draw curves showing the special age incidence of each, and each curve has its own special features. Now during an influenza epidemic the pneumonia curve is found to be modified so as to take on some of the characters of the influenza curve, thus affording corroborative evidence of a conclusion already reached both in this country and in

Germany, that influenza may occur sometimes as an apparently primary pneumonia

The remaining tables deal with the data afforded by the epidemics of 1891 and 1892 in this country and abroad. That of 1891 is shown to have been much more fatal, especially at advanced periods of life, than that of 1890, while that of 1892, here treated of with less fulness than the preceding, seems to have been of still greater severity. Those who would follow Dr Dixey into the details of these outbreaks must study the work for themselves. It is a contribution to statistical literature of very great value, and will save an infinity of labour to those engaged in the study of influenza.

A word of praise must be bestowed in conclusion upon the graphic charts with which the tables have been illustrated, those in particular which deal with the mortality curves from influenza and its allied diseases. These have been calculated and mapped out as percentage deviations from the mean, and show the main facts at a glance in a way which mere columns of figures fail to do. Those also which illustrate the age incidence of the diseases in question are of great value.

#### OUR BOOK SHELF

*An Elementary Text-Book of Hygiene* By H. Rowland Wakefield (London: Blackie and Son, 1892)

THE appearance of yet another elementary text-book upon the subject of Hygiene has the effect of aggravating the *embarras de richesses* which already obtains in this department of study, one is therefore justified in questioning the utility of the present volume, and on reading in the preface that it is adapted to the requirements of the Science and Art Department, there is all the more matter for surprise at its appearance in the face of three other publications—each better than the present—which have been written to meet the same end.

The manual is well printed and concisely written, and a surprising amount of matter is condensed within its tiny compass. This latter fact, however, is not entirely a matter for congratulation, for apart from making the book "dry reading," it must have the effect of rendering it in many places difficult of comprehension to those for whom it is intended, *i.e.* those who approach the subject with no prior knowledge whatever.

And thus it comes about, that in less than 200 small pages the whole range of Hygiene is surveyed, including chapters upon Eyes and Sight, School Hygiene, House Sanitation, Personal Hygiene, Parasites, Infectious Diseases, Accidents and Injuries.

Though the material given has been on the whole well selected and carefully compiled, the work is a little uneven, one finds seventy-three pages devoted to "food," whereas "water" is dismissed in seventeen, and "sewage and its removal" in eleven.

Here and there is evidence of the fact that the author is not of the profession to which Hygiene holds a filial relation, and that he was not quite at home with some of the departments of the subject—even in their elementary form—which he had set himself the task of handling, the very few errors and ambiguities which this fact is accountable for, are, however, too trivial to much affect the general accuracy of the book.

The small work will doubtless suffice for the examination requirements of those for whom it is intended, but the brevity and superficiality of treatment which is so frequently apparent within its pages, will not justify one in recommending it to those who wish to lay a good and useful foundation for a study of the science of Hygiene.

NO. 1211, VOL. 47]

*Ostwald's Klassiker der Exakten Wissenschaften* Nos. 38-40 (Leipzig: W. Engelmann)

WE are glad to note the addition of three volumes to this admirable series. No. 38 is the second part of the original account of the photochemical researches of R. Bunsen and H. E. Roscoe (1855-59). The other volumes are translations of a paper by Pasteur on the minute organic bodies in the atmosphere (1862), and of papers by Lavoisier and Laplace on heat (1780 and 1784). In all the volumes there are figures in the text.

#### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### Geographical Names

AS the names of places given to the public with the authority of the Geographical Society of London are very apt to be accepted by geographers and be ultimately inserted in atlases and works on geography, I have to call attention to the paragraph "Nomenclature of the Karakoram Peaks," under "Geographical Notes," p. 857, in the December number of the Proceedings of the R.G.S., 1892, which I have lately read. It is to be regretted that so much reliance and importance has been placed on what a native drew on the sand, and the names he gave to various peaks. Natives are not always to be depended upon, not even when the topographical features are in sight, and unless verified from other and independent information, the names they give cannot be implicitly trusted and placed on record, as is so well exemplified in this case. The traveller must also have a considerable knowledge of the native languages or he may be very much misled. As fortunately I know both the places bearing the names given for two very conspicuous peaks, it may not be too late to prevent these names thus put forward from being accepted and perpetuated. "Skeenmung" or "Skinmang" is the name of a comparatively level piece of somewhat grassy ground at the great bifurcation of the Punmah Glacier, the name itself is expressive and is derived from "Skeen" an ibex, and "Mang," a level place in Balti = Marg, Kashmiri, Maidan Hindustani—which disposes of it as a likely designation for a peak.

Next we have "Chiring" given as the name of K2, the second highest peak in the Himalayas, quite as inaccurate, for it happens to be the name of another camping spot or bivouac at the end of a spur and about halfway between Skeenmang and the Mustakh pass, as used about the period I was there (1860). It is situated just above a very narrow part of the glacier, where its action is most marked on the rocky sides. "Chirwa" in Hindustani is to rend, tear, and Chiring Gause is the name of all that portion extending six miles up to the main watershed.

Shalford Park, Guildford, January 7

#### The Weather of Summer.

THE number of days with rain, in summer, at Greenwich, during most of this century, has been subject to a pretty regular fluctuation. The curve (from 1825) having been smoothed by means of five-year averages, we obtain that shown in the diagram. And putting with it a curve of sun-spots, we find a strikingly definite correspondence (somewhat "lagging" in character) throughout at least four of the sun-spot cycles, the rain day maxima coming soon after the sun-spot maxima, and rain day minima soon after sun-spot minima. In recent years, however, the curves appear to have got out of step (so to speak) with each other; so that, *e.g.* we find a rain day maximum in 1880, two years after the sun-spot minimum of 1878, and a rain day minimum in 1885, two years after the sun-spot maximum of 1883.

I do not remember to have seen the facts of our summer weather put in this way. But it is well known that, in the discussions which arose some time ago about sun-spots and rainfall, there appeared some reason to believe that in the period of

those four earlier sun-spot cycles, at least, we had had, on the whole, wetter years about sun-spot maxima than about the minima. A good deal was written on the subject (as your own columns show) in the seventies, and the data used seem to have been generally those of annual rainfall. Of late, apparently, the matter has attracted less notice, for the reason (I suppose) that the correspondence referred to has not been maintained, and recent facts have seemed rather against the theory of a causal relation between the two orders of phenomena.

Thus the teaching of the curve here given appears to harmonize, in general, with known facts about annual rainfall. I do not propose to try and weigh the data so far as they may be considered to favour the theory just indicated (earlier and greater part of the curve), nor the data which may be considered adverse (in the short, later part). It seems to me that the curve may be usefully studied *per se*, apart from any relation to sun spots. Thus we might note the fact that all those maxima where our summers have got to a turning point from wet to dry have been quite near the beginnings of the decades. The dates are 1830, 1839, 1850, 1861, and 1880. The curve ends at 1890 (the final point representing, of course, 1888-92), and the position of this point, together with the date, seem to warrant our

Smoothed curve of rain days in Summer at Greenwich, with curve of Sun-spots

looking for an early descent of the curve, and a commencing series of (on the average) drier summers than we have had lately.

We might also note that the minima of the curve have ranged from the fives to the eights. Thus we have, 1827, 1835, 1845, 1857, 1868, 1885. Should the recurrence continue, we might look for the next minimum about 1895-1898. Of course there may be difference of opinion as to the strength of the presumption here afforded for such a forecast, and no good reason is offered (beyond experience) why the curve should now take the course roughly indicated.

It is not at variance with the above view that there is reason, it would appear, to anticipate soon a series of wetter years. In an article contributed to the *Times* of October 22 last year (cited in *NATURE*, vol. xlv. p. 630) Mr. Symonds says: "There is no doubt that since 1887, at all events, the rainfall over England has been much below the average, and a consideration of all the facts leads to the conclusion that such a period of scarcity is very likely to be followed by one of abundance, and that the coming few years will probably be more rainy than those recently experienced, although possibly the increase will not occur in the summer months—at a time when it would be most noticed."

A B M

#### "Aminol"

My attention has only now been called to the letter of Dr Klein, which appeared in *NATURE*, ante, p. 149.

To the remarks referring to "Aminol" (with Periodate I am in no way concerned) I desire, with your kind permission, to make the following reply, as they contain inaccuracies which, if not corrected, must do me injury.

The samples of "Aminol" alluded to by Dr Klein were sent by me to a number of medical practitioners who had kindly consented to give it a trial. The strength of the samples was 1 in 5000.

Dr Klein has carried out between September, 1890, and March, 1891, five separate consecutive series of experiments with "Aminol," with the object of testing its applicability to the treatment of certain external disease processes. His results are recorded in a report, the summary and conclusions of which were published last year with his full approval. The strength of solution employed in the first four series (which were only of a tentative nature with a view to arrive at a proper strength of solution for practical application) was 1 in 6000, in the fifth series a solution of the strength of 1 in 600 was used. Dr Klein's letter leads one to suppose that he operated only with the latter strength.

The pathogenic germs selected for testing the power of the disinfectant were spores of *Bacillus anthracis*, sporeless *Bacillus anthracis*, *Staphylococcus aureus*, *Bacillus diphtheriae*, and *Streptococcus erysipellatis*. Amongst the results obtained with the solution of the strength of 1 in 6000 his report mentions the following: In Series IV, "On *Staphylococcus aureus*, which may be taken as the most resistant microbe amongst those associated with surgical and other external disease processes, the "Aminol" solution (1 in 6000) did produce an effect, though a limited one, after two hours already, and after twenty four hours destroyed the microbes." In Series I - "Aminol" solution (1 in 6000) kills the *Bacillus diphtheriae* in two hours. This was confirmed in Series III." In this connection it deserves to be noted that I possess already ample evidence, which will be published in due course, of conspicuous successes obtained in practice not only with the solution of the strength of 1 in 5000, but also with dilutions of the same, even to 1 in 20,000.

Dr Klein's statement of the results which he obtained with "Aminol" in the strength of 1 in 600 is misleading. He says "Spores of *Anthrax bacilli* remained unaffected after eight hours, only after an exposure of twenty-four hours did the number of living spores decrease, but some escaped disinfection even after so long an exposure. Now what are the facts? I quote from Dr Klein's report —

"Spores of <i>Bacillus anthracis</i> after	} good growth
1, 2, 8, and 12 hours	
"Spores of <i>Bacillus anthracis</i> after	} growth reduced
24 hours	

Is it putting the case fairly or even clearly, seeing that no tests were made between twelve and twenty-four hours, to say "only after twenty four hours did the number decrease," and seeing that only 6 per cent remained after twenty-four hours? Is not that a decrease practically amounting to disinfection? Would it be extravagant to assume that the insignificant percentage remaining would be eliminated after a very little longer exposure (say another hour), and is there any doubt that a solution of the strength of 1 in 500 or 1 in 400 would have accomplished complete disinfection in a much shorter time than twenty four hours? But in order to illustrate the significance of the results actually obtained with this solution of the strength of 1 in 600, let us see which other disinfectants can kill anthrax spores in twenty-four hours. I quote from "Koch on Disinfection," abstracted and translated by Whitelegge, published by the New Sydenham Society —

(1) "For practical purposes a disinfectant should not require much longer than twenty-four hours"

(2) "Except chlorine, bromine, and iodine, only mercuric chloride, osmic acid, and potassic permanganate (5 per cent) destroyed anthrax spores within twenty four hours. Since a 5 per cent solution of permanganate is inadmissible for disinfection in bulk, and osmic acid is out of the question, we have left only mercuric chloride and iodine, bromine, and chlorine."

The strengths in which the above-named substances succeeded in destroying anthrax spores in twenty-four hours are stated in Koch's tables thus —

Permanganate, aqueous solution	5 per cent	(1 in 20).
Bromine	"	2 " (1 in 50).
Chlorine	"	?
Iodine	"	?
Mercuric chloride	"	1 per cent (1 in 100).
Osmic acid	"	1 " (1 in 100).

Now put against this the fact, quoted above, that Dr Klein found "that 'Aminol,' strength 1 in 600, killed 94 per cent of anthrax spores in twenty-four hours," and further (I am quoting his report again), "that this solution is a perfectly harmless fluid as regards the human organism; therefore no undesirable disturb-

ances could ensue owing to its being absorbed, this is well known to be the fact with some antiseptics, as in carbolic acid applications or in the use of perchloride of mercury."

Does not all this clearly establish the claim of "Aminol" to be called not only a true disinfectant, but a most potent and a most safe one at the same time?

But with all this (I mean what relates to its effect on anthrax spores) its application in medical and surgical practice has nothing to do, unless it be to demonstrate its comparative potency, for, as Dr. Klein himself points out in his report, "The spores of *Bacillus anthracis* may be left out of consideration, as they do not occur in the living body, under these conditions the *Bacillus anthracis* is always sporeless, a malignant carbuncle of the skin contains the *Bacillus anthracis* only in the sporeless state, and in infection with anthrax generally the bacilli are always in the sporeless state both in the blood and in the tissues."

What is of real importance in practice is the effect of "Aminol" on the other pathogenic germs on which Dr. Klein has tested it. And here again his letter states the case in a manner which is apt to mislead. "*Anthrax bacilli*, *Staphylococcus aureus* and others were destroyed, but only after a lengthy exposure."

Now what does his report say? "Series V. From this series it will be seen, therefore, that the solution used in the same (1 in 600) acted very differently from that used in the previous experiments (1 in 6000) inasmuch as the *Staphylococcus aureus*, which was not killed heretofore in eight hours, was in this instance completely disinfected in that time, and was considerably reduced even in one hour. The sporeless *Bacillus anthracis*, *Bacillus diphtheriae*, and *Streptococcus erysipelatis* were killed in one hour." Can it be fairly said, then, that these were killed only after lengthy exposure, and does the word "only" apply at all to the one-hour results, when it is considered that there was no test made under the one hour? What is there to show that those of which there was no growth after one hour's exposure to the disinfectant had not been killed after ten minutes already?

Does it not look, then, as if Dr. Klein had penned his letter without consulting either his notes or his report?

A word in conclusion. Dr. Klein, for whom perhaps nobody entertains a higher personal regard than myself, may rest assured that the designation, "a true disinfectant," is meant by me to apply only to such strengths of solutions of "Aminol" as can compete with those substances and their respective strengths to which Koch has accorded that appellation. Nor need he to apprehend that anything has been or will ever be done by me intentionally committing him to what is not fully warranted by his actual results as recorded in his authorized published report.

HUGO WOLLHEIM

101, Leadenhall Street, E C, January 2

THE point at issue between Mr. Wollheim and myself is a very simple one, and needs no long explanation on behalf of Mr. Wollheim. As you will see from the letter which you kindly printed in *NATURE*, ante, p. 149, Mr. Wollheim, without my authority, has sent round a leaflet with my name on it, accompanying bottles of "Aminol," stated to be "a true disinfectant."

1. On this leaflet my name is introduced in a somewhat misleading manner, for it quotes to a large extent from my reports on the lime and brine experiments on microbes without saying so, but leaving the reader to infer that these reports of mine refer to "Aminol."

2. Mr. Wollheim never asked my permission or informed me of his intention of sending with each sample bottle of "Aminol" such a leaflet. It is unnecessary to say that had he asked me whether he could use my name on a wrapper of a patent medicine I should have emphatically answered no. He has recently informed me that he has cancelled the leaflet.

3. The samples of "Aminol" sent out were of the strength of 1 in 5000, the experiments in which I showed that "Aminol" possesses a certain disinfecting power were made with a strength of 1 in 600. This strength did not kill spores of anthrax in 12 hours; 1 in 6000 did not kill *Staphylococcus aureus* in 8 hours.

\* A substance which, like the "Aminol" sent out (viz. 1 in 5000), cannot kill *Staphylococcus aureus* in 8 hours, and has practically no effect on spores of *Bacillus anthracis* cannot be considered "a true disinfectant."

To show that Mr. Wollheim had a very strange idea about

NO. 1211, VOL. 47]

the whole matter, one has only to compare the actual facts of the case, as regards "Aminol" of the strength of 1 in 5000, with the motto put on the leaflet and the inscription on the label of the samples. For Mr. Wollheim quotes Koch to the effect that no disinfectant can be called a true disinfectant that does not kill spores, and notwithstanding that I have shown that "Aminol" even of the strength of 1 in 600 cannot kill spores in 12 hours, yet Mr. Wollheim advertises the "Aminol" of the strength of 1 in 5000 as "a true disinfectant." A true disinfectant kills spores after short exposure, a substance that requires many hours to do so cannot claim the name of a specific disinfectant. Vinegar, dilute acids, alkalies, and a host of substances affect spores after exposure for many hours (8, 12, and 24 hours), yet no one would consider these substances as specific disinfectants.

Again, a substance used in a certain strength (say 1 in 600) may have considerable disinfecting power on non-spore bearing microbes, with or without having any conspicuous action on spores. The same substance more diluted (say 1 in 5000) may have retained such action only to a very insignificant degree. Take for instance perchloride of mercury, while this substance is a powerful disinfectant when used in the strength of 1 in 500, 1 in 1000, even 1 in 2000, it has greatly less effect when used in more increased dilution.

No one is justified in advertising perchloride of mercury of the strength of 1 in 100,000 as "a true disinfectant," knowing that 1 in 500 or 1 in 1000 only can be so called. How much more does this hold good for a substance like "Aminol," which even in the strength of 1 in 600 does not kill the spores of anthrax in 12 hours, a period which for practical purposes of disinfection is out of the question.

E. KLEIN

19, Earl's Court Square, S W, January 9

### Super-abundant Rain

IN *NATURE* of November to the fact that "very nearly one-third" of the annual rainfall fell in one month at Nant-y-Glyn, in North Wales, is recorded as "remarkable."

But at Peshawar, on the north-west frontier of India, we received during last August a rainfall of 17.75 inches, the average local annual fall, calculated from the last fifteen years, being 13.51 inches.

We therefore had very nearly sixteen months fall in one month, and by far the largest portion of this fell in ten days of the month.

I need hardly add that the whole valley was flooded, and that we have since paid for our super-abundant rain in the form of very prevalent and fatal malarious fever.

H. COLLETT

Peshawar, December 19, 1892

### Earthquake Shocks.

THERE were two unmistakable shocks of earthquake on the afternoon of Tuesday, January 3, the first at 2h 15m 15a. G. M. T., and the second at 2h 17m. I was sitting in a railway carriage at Severn Junction Station waiting for the Bristol passengers, when I felt a sensible upward movement of the seat (as if pushed from below) and saw the carriage sway. The movement was from south to north (i.e. at right angles to the railway). This was repeated four times in about six seconds. At 2h. 17m. there were two more (less strong) shocks. The carriage was placed in a siding, and there was no train at the station, and the air was calm and frosty. Ice was said to have cracked near here at this time.

E. J. LOWE

Shirenewton Hall, Chepstow

### A Brilliant Meteor

ON Wednesday, January 7, at about 6.35 p.m., I was fortunate enough to see a brilliant meteor descending a little north of Castor. My attention was drawn to it by the brilliant light it threw over the country. The head was a ball of dazzling white and the tail yellow, with red streaks. It disappeared before reaching the earth, and I heard no report or rushing sound whatever.

As the duration was only a few seconds the above are more impressions than observations.

W. POLLARD

Pitton, Herts, January 7

### CHEMICAL SOCIETY'S MEMORIAL LECTURES

AT an extra meeting of the Chemical Society, held on December 13 last, this being the first anniversary of the death of Stas, a paper was read and discussed which had been prepared for the occasion by Prof J W Mallet, F.R.S., of the University of Virginia, U.S.N.A.—himself a high authority on atomic weight determinations, and well known to chemists through his papers on the atomic weights of aluminium and gold, published by the Royal Society of London.

The lecture marks a new departure in the work of the society. Hitherto our learned societies have been in the habit of publishing more or less complete—it would probably be nearer the truth to say incomplete—obituary notices of their foreign members. The Chemical Society has come to the conclusion, however, that inasmuch as its foreign members are always men of great distinction who, as a rule, have lived a considerable number of years after accomplishing their life work, it will be to the advantage of its fellows and of chemists generally, if the obituary notices of foreign members take the form of critical monographs of the subjects with which they have principally dealt.

The anniversary of the death of the foreign member is obviously the most appropriate occasion for the delivery of such a lecture. During the past year the society has lost two of its foreign members. Hermann Kopp, noted as an historian, as well as on account of his very numerous exact determinations of atomic volumes and specific heats, and A W von Hofmann. The life and work of the first mentioned will form the subject of a lecture to be delivered on February 20 next, by Prof Thorpe, the Treasurer of the Society, than whom no one is more qualified to undertake the task. Prof Thorpe is not only a pupil of the deceased chemist, but has reverently followed in his footsteps—having very largely extended Kopp's observations on atomic volumes in an elaborate investigation, the importance of which was recognised by the Chemical Society in 1881 through the award to him of its first Longstaff medal.

Von Hofmann, although originally a foreign member, became an ordinary member of the Chemical Society on coming to England as professor at the school in Oxford Street, long since merged in what is now known as the Royal College of Science, London. Hofmann was never again regarded as a foreigner; he served the society both as foreign secretary and as president, filling one of the vice-chairs during the remainder of his life. It is felt that owing to the special nature of his relations to the society and to English chemistry, it will be necessary to deal with his case in an exceptional manner; it is therefore hoped that in May next Lord Playfair—who was so intimately connected in his early days with chemical science and with the society—in the first place will picture the state of affairs chemical at and prior to the time of Hofmann's arrival in England. Sir F Abel, Hofmann's first pupil and assistant, will follow with an account of Hofmann at the Royal College of Chemistry, calling to his aid for this purpose the remaining friends and pupils of Hofmann. The coal-tar colour industry, which has now attained such important dimensions, it is well known, had its origin in the Oxford Street laboratory, and Dr Perkin—its parent—has consented to sketch the history of its development. In this manner it is hoped to impart considerable "local colour" to the Hofmann memorial lecture, thereby distinguishing it from the notice which is being prepared by the German biographers.

Passing now to Prof. Mallet's lecture on Stas, which is of considerable length, as it will occupy fully sixty pages in the Society's Journal. The biographical portion is brief, as a number of such sketches have already been

published. Stas was born at Louvain on August 21, 1813. He graduated as Doctor of Medicine. His taste for chemical research was evidenced in 1835, when, together with a friend, he investigated in an attic of his father's house the crystalline substance phloridzin which they had extracted from the root bark of the apple tree. He continued the study of this substance in Dumas' laboratory in Paris, and it is an interesting proof of the acumen of Berzelius that in his annual report on the progress of chemistry he referred to this first research made by Stas with praise, and a prediction of future eminence for the author.

The starting-point of the long train of research with which his name will ever be associated was the redetermination of the atomic mass of carbon which Dumas and he together undertook, in order to explain the fact, noticed by Liebig and others, that the sum of the carbon and hydrogen found in hydrocarbons by the combustion process, as calculated from the carbon dioxide and water, not unfrequently exceeded the quantity of material analyzed. As the result of this investigation, which was carried out with unprecedented care and the most elaborate precautions, the value hitherto accepted for carbon on the authority of Berzelius (76.432 O=100) was considerably reduced (to 75.005). In 1840 Stas was appointed Professor in the École Royale Militaire at Brussels, he held this post for more than a quarter of a century, until an affection of the bronchial tubes and larynx obliged him to give up lecturing. He then received an appointment in the Mint, but resigned this in 1872 on political grounds, and withdrew into private life. He appears to have been a man of great independence of character.

Apart from his atomic weight investigations Stas did much work of value in other departments. His method of separating alkaloids from organic messes—no other name is applicable—which has been of such service in subsequent toxicological inquiries, was devised in 1850, in the course of the inquiry into the celebrated Bocarmé nicotine poisoning case. He examined into the methods of hydrolysing fats for the purpose of a report on the chemical section of the London 1862 Exhibition. In connection with the preparation of international standards he took an active part, along with Devile, in the inquiry into the properties of the platinum metals. It is known also that he did important work for his Government in investigating alloys for use in the construction of artillery.

Prof Mallet prefaces his account of Stas's special investigations by an historical survey of the fundamental ideas which have gradually led up to the question, What is the mass of an atom of a particular element? Even in and beyond the days of Cavendish and Priestley the fact that atmospheric air was found of constant or nearly constant composition was long a stumbling-block in the way of clear distinction between a homogeneous compound and a uniform mixture. To the labours of Van Helmont, Boyle, and Boerhave much credit is due for the gradual advance towards the doctrine of the conservation of matter. The discoveries of Black and Cavendish brought it further into view, and it assumed its due importance and began to receive universal recognition with the constant appeal to the balance which Lavoisier made and taught others to make. Next came a comparison of the quantities of different substances, at first chiefly the then known acids and bases, which would enter into combination with each other. Proust, in the course of his controversy with Berthollet as to the fixedness of combining proportions, had observed that in certain cases it was true that in different compounds, consisting of the same constituents, for a fixed quantity of one constituent, the different quantities of another constituent bear to each other a simple multiple or sub-multiple relation. To Dalton, however, belongs the honour of announcing the principle as a general one, and of basing upon it a true chemical atomic theory of the nature of matter. Berzelius,

in the early years of the present century, with apparatus in many respects inferior to that of the present day, and with scarcely any aid from chemical manufacturers in preparing pure materials and reagents, but with unsurpassed manipulative skill and the most honest criticism of his own work, produced the first fairly trustworthy list of numbers representing the proportions by weight in which the elements combine. Berzelius began work in this direction in 1807, his attention having been attracted by Richter's investigations, but soon afterwards he became acquainted with Dalton's new atomic theory of the nature of combination, and appears to have been impressed with its great importance, and at the same time with the need of more exact experimental data for its support and development. The wonderful accuracy of Berzelius's work generally is illustrated, as Prof. Mallet points out, by the fact that his number for oxygen, 16.021, becomes 15.894, almost exactly agreeing with the latest determinations of the present day, if the weighings of Dulong and Berzelius's three experiments on the synthesis of water be corrected for the buoyancy of the air. Since Berzelius many other chemists have worked in the same field, but his most worthy successor in such labours has undoubtedly been Stas. With greatly better resources in the way both of apparatus and material, with equal earnestness in seeking for the truth, with equal intelligence and skill he took up the task which became that of the largest part of his scientific life, and for a more limited list of elements than Berzelius had investigated, produced results of a degree of accuracy which it is high praise to say would have delighted no one more than Berzelius himself. He aimed at the determination with greater precision than any one before him had attained of the atomic weights of some ten or twelve of the elements. But by so determining these constants he endeavoured also to settle several general questions of fundamental importance in regard to matter as studied by the chemist.

Thus it has generally been assumed as true beyond dispute since the early part of the present century, that the mass of an atom of a given element is a constant quantity. This has, however, occasionally been doubted, and Stas himself considered the question as one requiring examination. His researches, however, lend no support to it. On this point Prof. Mallet expresses himself strongly in favour of the orthodox view.

Assuming that the atomic weights are immutable values, the question arises, Are they commensurable? This is the much-discussed hypothesis of Prout, the origin and development of which is very fully discussed by Prof. Mallet. A widespread feeling at one time undoubtedly existed among chemists that Prout's hypothesis, that the atomic weights of the other elements are integer multiples of that of hydrogen, if not true in its original form would ultimately prove to be so at least in a modified form. That Stas began his work under the influence of this feeling is clear from his own words—

"Je le dis hautement lorsque j'ai entrepris mes recherches, j'avais une confiance presque absolue dans l'exactitude du principe de Prout."

But his experimental results clearly contradicted the hypothesis, and he satisfied himself that the atomic weights of the elements which he determined with such precision could not with truth be represented by integer multiples of the atomic weight of hydrogen, or the half or the fourth of this unit. In his own words,—

"Aussi longtemps que, pour l'établissement des lois qui régissent la matière on veut s'en tenir l'expérience, on doit considérer la loi de Prout comme une pure illusion. La simplicité de rapport de poids que pré-suppose l'hypothèse de Prout entre les masses qui interviennent dans l'action chimique, ne s'observe donc point dans l'expérience; elle n'existe point dans la réalité des choses."

The great majority of chemists—Prof. Mallet remarks—at the present day, are probably agreed in believing that the hypothesis of Prout has been shown by Stas to be untenable. But the fact that so many well determined atomic weights, referred to hydrogen as unity present numbers *nearly approaching integers*, is very striking and calls for further investigation. Stas himself is quoted as admitting this much. Prof. Dewar, in the course of the discussion after the paper was read, drew special attention to this question and gave several most striking instances of the nearer approach to whole numbers which resulted from a recalculation of the accepted values, using the lower value for oxygen (15.87) which so many recent researches tend to support, although on the other hand, of course, some of the values now near to whole numbers are considerably thrown out. Evidently there is ample opportunity for further experimental investigation of this all-important problem, and it is impossible—notwithstanding the extraordinary degree of accuracy attained by Stas—to formulate any final conclusion. The supreme interest attaching to the problem was clearly recognised by Stas himself, as the following words show—

"Au point de vue de la philosophie naturelle, la portée de l'idée de Prout est immense. Les éléments des corps composés que nous considérons comme des corps simples en égard à leur immutabilité absolue pour nous, ne seraient eux-mêmes que des corps composés. Ces éléments, dont la découverte fait la gloire de Lavoisier et a immortalisé son nom, peuvent être considérés ainsi comme dérivant de la condensation d'une matière unique nous sommes naturellement conduits à l'unité de la matière, quoi qu'en réalité nous constatons sa pluralité, sa multiplicité."

This quotation is almost alone sufficient to show that Stas was a philosophical chemist of the highest order, and not a mere mechanical worker, as has sometimes been supposed, his unwearied attention to minutest details has undoubtedly served to completely overshadow the philosophical motives and aspirations by which he was guided.

Stas also endeavoured to obtain evidence with regard to the possible dissociation of the elements at high temperatures and to this end purified his materials with every imaginable precaution. The skill with which he carried out his operations is attested by the statement made by Mr. Crookes, the chairman at the reading of Prof. Mallet's paper, that he had seen in Stas's laboratory a large mass of potassium chloride, which Stas had been years in preparing, and in which he had failed to find a trace of sodium even spectroscopically—such an achievement appears almost inconceivable to the chemist. Stas, in fact, in the course of his work investigated the methods of analysis to be used with a degree of rigour, and discovered and applied refinements upon older methods of experiment with a degree of patience and skill, such as had never before been used in chemical investigation. Only those who are thoroughly conversant with such work can fully appreciate his labours, they probably will agree that owing to the multitude and diversity of the precautions to be taken, his work is the most difficult hitherto attempted, and that he stands unsurpassed among all who have undertaken the execution of exact physical measurements.

A lengthy section of Prof. Mallet's paper is devoted to the consideration of the objects to be aimed at and the methods to be pursued in future work. He advocates the repetition by competent hands of some one at least of Stas's fundamental results, calling attention to Stas's own emphatic expression of the wish that this should be done. It is also most important that no distinction should be made between rare and common elements, and that the atomic weights of all should be determined with the least possible delay and the highest attainable degree of accuracy. Certain of the elements particularly call

For a more searching and exact investigation of their atomic masses, *e.g.* elements such as tellurium, which occupies a position in the periodic system not in harmony with its atomic mass, and cobalt, which plainly occupies the intermediate position between iron and nickel, and therefore should be intermediate in atomic mass.

In a number of cases the accepted value is based on the investigation of but a single interchange, the value for iron, for instance, being practically based on the results obtained on converting the metal into ferric oxide, and *vice-versâ*, and the relation of hydrogen to oxygen having been established by the reduction of cupric oxide. It is desirable that in such cases other and independent methods should be resorted to, *e.g.* that oxides of a number of metals other than copper should be reduced, with the object of detecting possible constant errors.

It is eminently desirable that an attempt be made to directly determine the ratio of hydrogen to each of the halogens without in any way bringing in the atomic mass of oxygen. Prof. Mallet suggests various methods deserving of study. Also it is very important that the metals of the yttrium and didymium groups should be further investigated. Prof. Mallet rightly terms the yttrium group the opprobrium of inorganic chemistry.

Nearly all that has been written hitherto in regard to the periodic relationship among the elements has involved the use of roughly approximate values only, but it is time that the foundation be laid for a more minute and critical study of the periodic system of classification. Anomalies in the classification as we now find it in our books, glimpses of more detailed relations than as yet clearly appear, tantalizing suggestiveness in so much of what is already before us, call for more precise determinations of the numbers we would discuss before we allow premature discussion to drift into mere fanciful speculation.

In regard to the methods which it is desirable shall be pursued in the determination of atomic masses, Prof. Mallet has much to say. He discusses the selection of processes, the purity of materials, the very numerous directions in which vigilance must be exercised in order to avoid extraneous or accidental causes of error, the quantities of material to be used, the practical precautions to be observed so as to secure accuracy of manipulation and in weighing and measuring, the mode of stating and calculating results, finally calling attention to the advantage to be derived from the application of greater working force and ampler means than can be commanded by private individuals to the determination of atomic masses, with reference to this last point, during the discussion on the paper, the opinion was freely expressed that it was undesirable that such work should be carried out in organized public or semi-public laboratories. The question is, no doubt, a difficult one to settle—such work demands a special temperament combined with genius of a high order and an infinite capacity for taking pains, qualities which must rarely occur united in a single individual. Moreover, in order that the value of a result may be appraised, it is essential to overlook every detail involved in the determination. Given the man, however, there can be no longer a doubt that every possible assistance he may require should be afforded him. It is marvellous that men like Berzelius and Stas, working all but alone and unaided, should have achieved results of such magnitude and universal importance—the moral effect of their example is certainly not less important than are the actual results of their labour.

The last section of Prof. Mallet's paper is devoted to the discussion of the form in which it is desirable finally to state the results. He here advocates the uniform substitution of the expression "atomic mass" for "atomic weight," on the ground that precision in language conduces to precision in thought—an aphorism

far too commonly disregarded by chemists. We have now clear conceptions of atoms having constant mass for the same element, of determinable difference of mass in the case of different elements, the several masses and numbers of which regulate the composition of all known substances and the products resulting from interaction among them. The atomic theory has advanced far beyond the condition of a mere working hypothesis on which chemists long stood with more or less uncertain feet, but even if this were not so, considering it, to use a common metaphor, only as a scaffold, there is no good reason, so long as we stand on it and work from it, that we should be careless about tying our scaffold-poles and nailing our planks.

Lastly, Prof. Mallet urges that all atomic masses shall be expressed in terms of the mass of the hydrogen atom taken as unity, objecting strongly to the change to  $O = 16$  which several writers have recently advocated, the most objectionable argument put forward in favour of such change being, he thinks, that the numbers we use are expressive of *ratios* only—that any figures are allowable which correctly express combining ratios, and that there are no reasons for using one set of figures rather than another save mere arithmetical convenience. This involves a grave error, as in adopting as unity the mass of a single atom of any particular element, preferably that one of which the mass is the smallest, we have reason to believe that we express the mass of all the others in terms of this as a really existent, definite, and constant quantity of matter. It is, indeed, difficult to understand when the scientific necessity in so many cases of taking hydrogen as the unit is realized, how the change to  $O = 16$  can be advocated except on the simple utilitarian plea that it is to the analyst's convenience.

Prof. Mallet's monograph is undoubtedly a most admirable exposition of the philosophical lessons to be learnt from the contemplation of Stas's labours.

### EXTINCT MONSTERS<sup>1</sup>

THE volume with this title treats of large animals. It is clearly and simply written, without any pretence at being scientific, and is an excellent book for boys and unlearned people who are curious to be informed upon the subject of fossil animals. It would have escaped criticism altogether but for emphatic words of praise in the preface, and one or two passages in which the author, with second-hand information, speaks authoritatively of predecessors who restored extinct types of life with the slender materials which were available forty years ago. The attraction of the volume and its novelty is a series of restorations of saurians and mammals drawn chiefly by Mr. Smit. These for the most part are based upon the restorations of skeletons made by Prof. Marsh, whose discoveries have inspired Mr. Smit's pencil as much as they have influenced the author's pen. There is not much anatomy beneath the skins of the "Monsters," and they have an aspect as though cotton-wool had taken the place of muscle, or as though the drawings were models for the "Lowther Arcade." This, however, is of less importance than the answer given to the question, Are they reasonably faithful to nature? It does not seem to me that they can claim this merit, they are only reasonably faithful to Marsh. Prof. Marsh draws an animal so as to give one type the maximum height to which the bones can be hoisted; while another is given the maximum length to which the remains can be extended. My own studies would not have led me to reconstruct one of the extinct reptiles upon the lines which are adopted in

<sup>1</sup> "Extinct Monsters." A popular account of some of the larger forms of ancient animal life. By Rev. H. N. Hutchinson, B.A., F.G.S., with illustrations by J. Smit and others. (London: Chapman and Hall, Ltd., 1892.)

these restorations. As an example of how a restoration should not be made, we may instance the figure of *Stegosaurus unguatus* (p. 104), in which the management of the limbs is out of harmony with the evidences of the muscular structure of the tail, and the supra-vertebral crest. The restoration of the *Scelidosaurus* from the Lias of England is unsatisfactory. There is no better ground for giving a kangaroo-like position to that animal than there would be for drawing *Teleosaurus* in the same position. The mobility of the neck as drawn is astonishing.

The restorations of mammals are happier. The subjects diverge less from existing types. And probably the most successful in the volume is the spirited restoration of *Sivatherium giganteum* from the Sivalic Hills, though the *Glyptodon* and Irish Deer are meritorious.

In the text the author is generally content with telling the story of the history of science; but he sometimes

British Museum (Natural History), handed on to the unlearned as representing the best available classification. On page 75, the author introduces a restored skeleton of *Megalosaurus*, which is attributed to Prof. Marsh. The skeleton certainly is not referable to *Megalosaurus*, which never has the pubic bones or the ilium constructed as in the figure. The restoration has been previously used in Nicholson and Lydekker's "Palæontology," and in Dr. Woodward's "Handbook to the Geological Department of the British Museum," but we do not remember any published authorization for the use of Prof. Marsh's name as authority for confounding *Megalosaurus* with the allied American type.

Another example of the same kind of interpretation occurs in dealing with *Stegosaurus*. It is said to have been proved that bones to which the name *Omosaurus* has been applied really belong to *Stegosaurus*, and that an unnecessary name has been disposed of. The ground

The four-horned extinct Mammal *Sivatherium giganteum*. The animal on the left is *Heladotherium*.

strays into less safe matter. Thus an account is given of the eye of the *Ichthyosaurus*. And it is urged that the bony plates exercised a pressure on the eyeball, so as to make the eye more convex, and improve the definition of near objects. The study of sclerotic defences does not support this interpretation; and in at least one generic division of the *Ichthyosauria* the sclerotic plates do not overlap at all, but join each other by their lateral sutural margins.

It is perhaps unfortunate that the author gives currency to nomenclature and classification of the terrestrial types of saurians which may not always prevail. If the genera with a bird-like type of pelvis are terrestrial representatives of birds, and the genera with a reptilian type of pelvis are terrestrial wingless representatives of *Pterodactyls*, then it may not be an advantage to have the *Dinosaurs* treated as a homogeneous group, or the divisions adopted by Prof. Marsh, or in the

on which this determination is made, not being stated; need not concern us now, but it is undesirable that a popular work, whose main merit is that it does not pretend to teach the facts of science, should appear to enunciate judgments on scientific problems. Having described the immense enlargement of the spinal cord in the sacral region of *Stegosaurus*, the author remarks — "So this anomalous monster had two sets of brains—one in its skull, and the other in the region of its haunches!—and the latter in directing the movements of the huge hind limbs and tail did a large part of the work." Remarks of this character are sure to be misunderstood, are out of place and incorrect.

The author has read much, and shown an excellent capacity for quotation, but has not always succeeded in using the newest results. He has conscientiously endeavoured to tell the story which is contained in his quotations, but beyond this he does not pretend, except

in the occasional use of supposed scientific principles as a means of accounting for facts of animal structure. He has dealt with a subject of great difficulty with commendable clearness, and will interest readers who would be unable to follow a more technical exposition of extinct types of life. H G S

### ENERGY AND VISION

THE interesting researches of Prof S P Langley on energy and vision have recently been published in the Memoirs of the American National Academy of Sciences. From this we gather that he was led to investigate the question by the fact that it was not generally recognized how totally different effects may be produced by the same amount of energy in different parts of the spectrum. Two series of experiments were necessary, the first to determine the amount of energy in each ray, the second to observe the corresponding visual effect. The energy was determined as heat by the use of the bolometer, the heat dispersed by a prism being very nearly proportionate to the energy.

In the second series of experiments a beam of sunlight from a siderostat passes through a small hole in a darkened room and falls on a slit with a standard width of 0.1 mm. It is then received on a collimating lens of 11.9 centimetres aperture and 755 centimetres focal length, after which it passes through a prism of about 60° refracting angle. The spectrum thus formed is reflected and brought to a focus on a second slit of one millimetre aperture by a concave mirror, any particular colour being adjusted on the slit by a rotation of the prism. This second slit is screened from all possible stray light by a dark curtain, and is used as a source of illumination for a series of numbers from a table of logarithms, which is attached to a sliding screen. The greatest distance from the slit at which the figures could be distinctly read was then determined, and the law of inverse squares applied. For the brighter colours of the spectrum, the light entering the first slit was reduced by an adjustable photometer wheel.

Actinometric measures were made during the progress of the photometric observations, and showed a solar radiation of 1.5 calories per square centimetre per minute, this naturally being an essential unit.

The energy necessary to give the bare impression of luminosity in different parts of the spectrum, expressed in terms of horse-power, was found to be roughly as follows, the *minimum visible* being defined as the feeblest light which is observed to vanish and reappear when silently occulted and restored without the knowledge of the observer —

	Horse-power
Violet ( $\lambda$ 400)	0.000000 000000 00018000
Green ( $\lambda$ 550)	0.000000 000000 00000075
Scarlet ( $\lambda$ 650)	0.000000 000000 00017000
Crimson ( $\lambda$ 750)	0.000000 000000 34000000

These values were derived from observations made by a single observer, Mr F W Very, and are, of course, subject to a large percentage of error.

The general results of the investigation may be best summarized in Prof Langley's own words —

"The time required for the distinct perception of an excessively faint light is about one-half second. A relatively very long time is, however, needed for the recovery of sensitiveness after exposure to a bright light, and the time demanded for this restoration of complete visual power appears to be greatest when the light to be perceived is of a violet colour. The amount of energy required to make us see varies enormously according to the colour of the light in question. It varies considerably between eyes which may ordinarily be called normal ones, but an average from those of four persons gives the

following proportionate result for seven points in the normal spectrum, whose wave-lengths correspond approximately with those of the ordinary colour divisions, where unity is the amount of energy required to make us see light in the extreme red of the spectrum near A, and where the six preceding wave-lengths given correspond approximately to the six colours, violet, blue, green, yellow, orange, red.

Colour	Violet	Blue	Green	Yellow	Orange	Red	Crimson
Wave length	400	470	530	580	600	650	750
Luminosity	1600	62 000	100 000	28 000	14 000	1200	1

It appears from this that the same amount of energy may produce at least 100,000 times the visual effect in one colour of the spectrum that it does in another.

If now it be inquired what the actual value of unity is in ordinary measure, we are able to give this also with a fair approximation, and to say that the *vis-à-vis* of the waves whose length is 7500 (tenth metres) being arrested by the ordinary retina, represents work done in giving rise to the sensation of the deepest red light of about 0.001 of an erg in one-half second.

### NOTES

THE Prince of Wales has consented to become Chairman of the Committee for the memorial of the late Sir Richard Owen, and to preside at a meeting to further the object, which will be held in the rooms of the Royal Society, Burlington House, on Saturday, the 21st inst., at half-past eleven o'clock. Admission will be by tickets, which may be obtained from Mr Percy Sladen, Linnean Society, Burlington House, W (who is acting as secretary to the Committee), or from Mr H Rix, assistant secretary of the Royal Society.

THE annual general meeting of the Royal Meteorological Society will be held at 25, Gre at George-street, Westminster, on Wednesday, the 18th instant, at 7.15 p.m., when the Report of the Council will be read, the election of officers and council for the ensuing year will take place, and the President (Dr C. Theodore Williams) will deliver an address on "The High Altitudes of Colorado and their Climates," which will be illustrated by a number of lantern slides. This meeting will be preceded by an ordinary meeting, which will begin at 7 p.m.

THE general meeting of the Association for the Improvement of Geometrical Teaching is to be held at University College, Gower Street, W.C., on Saturday, January 14, the Rev C Taylor in the chair. At the morning sitting (11 a.m.) the report of the Council will be read, the new officers will be elected, and several candidates will be proposed for election as members of the Association. After the conclusion of the formal business Mrs Bryant will give "A Model Lesson on Geometry, as a Basis for Discussion." After an adjournment for luncheon at 1 p.m. members will re-assemble (2 p.m.) to hear papers by Mr G. Heppel on "The Use of History in Teaching Mathematics," and Mr F. E. Marshall on "The Teaching of Elementary Arithmetic." Members who wish to have any special matter brought forward at the general meeting, but who are unable to attend, are requested to communicate with one of the Honorary Secretaries. All interested in the objects of the Association are invited to attend.

DR. LUDWIG BECKER has been appointed to the chair of astronomy at the University of Glasgow.

THE Comet Medal of the Astronomical Society of the Pacific Coast has been awarded to Mr Edwin Holmes, of London, for his discovery of a new comet on November 6.

ON Tuesday next (January 17) Prof. Victor Hensley, F.R.S., will begin a course of ten lectures, at the Royal Institution, on "The Functions of the Cerebellum and the Elementary Prin-

ciples of Psycho-Physiology" The Friday evening meeting will begin on January 20, when Prof Dewar, F R S, will give a discourse on "Liquid Atmospheric Air"

THE severe frost which set in just before Christmas was succeeded by a rapid rise of temperature in Scotland on Friday, but in England the thermometer did not rise much above the freezing point until about twenty-four hours later. On the 5th and 6th instant the thermometer fell below 10° in many parts of Great Britain, and snow was falling in Scotland, which afterwards spread to many parts of England. The absolute shade minima recorded were—2° at Braemar, and 2° at Fort Augustus, in the north of Scotland. The distribution of pressure was unusually high over Scandinavia and northern Europe (inadvertently referred to in our issue last week as over these islands) having reached about 31.3 inches in Central Russia on the 4th, while areas of low pressure lay over the Gulf of Genoa and the south-west of Ireland. The latter depression gradually extended eastwards, causing strong easterly gales on the Irish coasts, while the anticyclone over Europe gradually gave way, the barometer at Haparanda on Monday being 1.5 inch lower than a few days previously. By Sunday all stations reported temperatures above the freezing point, while in the south west of Ireland the maxima reached 47° and in the south of France even 63°. These changes were accompanied by rain in most parts of the country, which added materially to the rapidity of the thaw. Bright aurora was seen on Monday night in Scotland and Ireland. On Tuesday an anticyclone from the north-westward was spreading over our islands, with finer weather and lower temperatures generally, frost occurring in the north of Scotland and the central parts of England. The *Weekly Weather Report* of the 7th instant showed that the temperature in the eastern and midland parts of England was 12° to 13° below the average for the week, at several of the inland stations in England the daily maxima were below 32° through the whole period.

AN enlightened Bengali, Babu Govind Chandra Laha, has contributed fifteen thousand rupees towards the expenses of the proposed snake laboratory at Calcutta. We may expect, therefore, that the institution will soon be in full working order. According to the *Pioneer Mail*, two main lines of research will be followed in the laboratory. So-called cures for snake bites will be tested under strictly scientific conditions, and the properties of the snake poison as such will be investigated. The laboratory will be the only institution of its kind in the world, and the Committee of the Calcutta Zoological Gardens, who have taken the matter in hand, expect that it will be largely resorted to by the scientific inquirers who visit India during cold weather. In accordance with the practice of scientific laboratories in Europe, a charge will be made for the use of the tables and instruments at a rate sufficient to cover working expenses. Work done on behalf of the Government will also be charged for according to a regular scale.

THE members and friends of the Society for the Study of Inebriety met on Tuesday to congratulate Dr. Severin Wiefobyski on having completed one hundred years of life.

PROF BAIN contributes to the new number of *Mind* an interesting sketch of the career of the late Prof G C Robertson, with whose name *Mind* will always be intimately associated. Prof. Bain includes in his article the admirable notice of Robertson written by Mr Leslie Stephen for the *Spectator*.

WE are glad to note the publication of a fifth edition, revised and augmented, of the Official Guide to the North Gallery at the Royal Gardens, Kew. It includes a short and interesting biographical notice of Miss North. A map is given to convey some idea of the extent to which her collection illustrates the vegetation of the temperate and tropical regions of the world.

NO. 1211, VOL. 47]

A NEW edition of the list of members of the Institution of Civil Engineers, corrected to the 2nd inst, the seventy-fifth anniversary of its establishment, shows that the aggregate number of all classes is 6341, an increase during the past year at the rate of 3½ per cent.

A PSYCHOLOGICAL laboratory has been established at Yale College, where Prof Ladd has for some years been lecturing on physiological psychology. *Science* gives an interesting account of the new institution, which has been placed under the charge of Dr E W Scripture, a pupil of Wundt. The laboratory consists of fifteen rooms, three of which, including an "isolated" room, are given over entirely to research. The isolated room is a small room built inside of another room, four springs of rubber and felt are the only points in which it comes in contact with the outer walls. The space between the walls is filled with sawdust as in an ice-box. The room is thus proof against sound and light, and, according to *Science*, affords an opportunity of making more accurate experiments on the mental condition than any yet attempted.

STUDENTS of ethnography will be interested to hear that Dr N B Emerson, of Honolulu, is preparing a full account of the Polynesian canoe. In a communication printed in the new number of the Journal of the Polynesian Society he points out that the various migrations of the ancient Polynesians and their progenitors, from whatever source derived, must have been accomplished in canoes or other craft, and that the *waa*, the *pahi*, &c, of to-day, however modified they may be under the operation of modern arts and appliances, are the lineal descendants of the sea-going craft in which the early ancestors of the Polynesians made their voyages generations ago. He holds, therefore, that a comparative study of the canoes cannot fail to shed light on the problems of Polynesian migrations and relationships.

AN interesting little paper on the destruction of wild birds' eggs, and egg-collecting, is contributed to the new number of the *Annals of Scottish Natural History*, by Col W H M Duthie. Collectors who require to be specially dealt with he groups in three classes—the aimless, the greedy, and the mercenary. In contrast with these is "the true collector," whom Col Duthie defines as "a naturalist, acquainting himself with birds, their habits, flight, migration, language, and breeding haunts, his egg collecting being only one of the means of acquiring this knowledge." The true collector should collect for himself, and should never receive an egg into his cabinet unless authenticated by an individual in whom he can implicitly trust. If all collectors were of this type, egg-dealers would cease to exist, and with them would disappear the tribe of hangers-on whom they maintain.

A GOOD study of the form of eggs has been recently made by Dr Nicolsky of St Petersburg. He constructs an abstract formula, by which different eggs can be compared without regard to absolute dimensions. Calling the longer axis 1000, he obtains a figure representing the ratio of the longest transverse axis to it, and another, that of the distance of the obtuse end from the "centre," or point where the longer axis cuts the plane of the equator, then forms a fraction with these two figures, and takes it as the formula of the egg. Various explanations have been offered for the different forms of eggs. Dr Nicolsky traces all to gravity. He considers that every egg not yet coated with a solid shell departs from the spherical form and elongates, simply because of pressure on it by the walls of the ovary. In birds which keep a vertical position when at rest (such as the falcon and owl) the soft egg becomes short through the bird's weight acting against the ovarian pressure. In birds which, like the grebe, are nearly always swimming, the egg lengthens, because the body weight acts in the same direction as the ovarian compression. Lastly, eggs become

pyriform (more pointed at one end than the other) in birds which, like the guillemot, often change their position, sometimes swimming and diving, sometimes perching on rocks, &c. An examination of all the eggs in the zoological collection of the St Petersburg University fully bore out these views. Dr Nicol-sky thinks it would be useful to test the theory by experimentation, birds being kept in a vertical or horizontal position at the laying time.

For twelve years (1878 to 1890) M. P. Plantamour made careful observations of the displacements shown by two spirit levels (one north-south, the other east-west), in the cellar of his house at Sécheron. The instruments were transferred to the Geneva Observatory, and the work resumed by M. Pidoux in April 1891 (after six months' interruption). M. Plantamour found that the mean air temperature had a preponderating influence in the oscillations observed, while some other factors of obscure nature were involved. The first year's data at Geneva (*Arch. de Sci.*) reveal an annual oscillation of the ground of the Observatory about an axis directed north-east and south-west, such that the south-east part sinks in summer and rises in winter. The east side went down till July 16, then rose gradually till the end of December (29), there after sinking again. The extremes were  $-4''\ 73$  and  $+4''\ 85$  (an amplitude of  $9''\ 58$ ). The variations of the south side were similar, but the amplitude somewhat greater. The north-south level showed some quite abnormal variations in the autumn of 1891, to which, however, the author does not attach great importance.

AN interesting contribution to our knowledge of the adaptation of structure to function in the human body is afforded in an investigation by Signor Minervini (of the Naples Society of Naturalists) of the blood-vessels of the skin in different parts. Portions of skin were prepared so as to show the exact structure of the chief arteries in them. The results are as follows—(1) The artery-walls of the skin in men are generally thicker than those of other organs. (2) This greater thickness is due generally, and during most of life, to thickening of the middle layer, but in childhood the outer, and in advanced years the innermost, layer is most developed. (3) The artery walls in the hollow of the hand, the finger-tips, and the sole, are, other things equal, thicker than those in the back of the hand, the forehead, the arm, &c. This greater thickness is due chiefly to a greater development of the middle layer, and in all ages of life. The arteries in the hollow of the hand in the case of occupations involving hard manual labour show a greater increase of thickness than in the case of those with little or no such work. In these cases all three layers of the artery are thickened, but the middle layer most. (4) In women all the chief arteries of the hollow of the hand and of the back of the hand are somewhat less thick than in men. The difference is not great, but occurs at all ages.

In a paper on the Santa Isabel Nitrate Works, Toca Chile, read lately before the Scottish Institution of Engineers and Shipbuilders, and now printed in the Institution's Transactions, Mr. G. M. Hunter has something to say regarding the origin of "caliche," as nitrate of soda is called in its native state. Some contend that "caliche" is a marine deposit, others that it is an animal deposit, while others say it is a vegetable deposit. Mr. Hunter holds the first of these views. The coast of Chile has several times been disturbed and upheaved by volcanic agency, and he suggests that a large tract of sea was enclosed and heaved up to the present height of the nitrate region, and there formed an inland sea, which, after a lapse of time under a tropical sun, evaporated, leaving the salts to percolate and form the beds of nitrate. From the formation of the ground, showing depressions and ravines leading to the sea, it is evident that immense volumes of water at some remote period have passed through them. In proof of this, Mr.

Hunter points out that no "caliche" is ever found in such places, the accepted opinion being that there has been a "wash out," as it is called. During a later period than that of the formation of the "caliche" great floods passed over the plains, as is shown by the deep tracks of rivers, and the smooth washed appearance of the surface. Such periodical floods are common in tropical, rainless regions, and would not call for special remark, but from the fact that wherever these river tracks or washed surface appear no "caliche" can be found. This is so well known that even the workmen never attempt to search for it in such places. The only surface indication for the presence of "caliche" is rising ground covered with small black stones. The "caliche" in its native state is white, very compact and amorphous, not unlike rock salt, but when rich in iodine it assumes various colours, according to the composition and quality of the iodine it contains. For example, at times it contains masses of bright yellow, red, or blue, and again wholly composed of a dull black colour, in which state it requires an expert to distinguish it from *costra* or rock.

MR. E. LOMMEL claims to have found a simple explanation of the Hall effect. A simple train of reasoning shows, he says, that the equipotential lines perpendicular to the lines of flow in a plate are also the lines of force due to the current. If iron filings are strewn upon the plate they will arrange themselves along the equipotential lines if the current be strong enough. On bringing the plate into a magnetic field these lines of force change their position. Hence the lines of flow, necessarily orthogonal to the lines of force, will also change in form and position.

ACCORDING to Dr. J. Böhm, the statement that *Phytophthora infestans*, the fungus which causes the potatoe diseases, hibernates in the tubers, is incorrect, nothing whatever being known about its mode of hibernation. He further states that the infection of the potatoes never takes place in the soil through the uninjured skin, but is always brought about through injury to the tubers by insects or snails. In potatoe heaps sound tubers can never be infected by their diseased neighbours. An infected potatoe either does not germinate at all or produces a healthy plant.

IN examining milk which is suspected to contain the tubercle bacillus it is usual to subject a sample of the milk to the action of a centrifugal machine after separating the fat. One method of working is described by Ilkewitach (*Münchener med. Wochenschr.* 1892). The casein in 20 c.c. of milk is coagulated with citric acid, and, after filtering, the residue is dissolved in a solution of sodium phosphate. The butter-fat is separated by shaking with 6 c.c. of an aqueous ether solution, and acetic acid is then added until the liquid is on the point of coagulating. It is then placed in a copper tube tapering at the bottom, and this tube is inserted in the centrifugal machine and turned at the rate of 3600 revolutions per minute for fifteen minutes. The bacilli collect at the narrow end of the tube together with other sediment and dirt. The liquid is poured off, and the sediment examined microscopically. Thörner (*Chem. Ztg.* 1892, pp. 791-2) gives another method, which is as follows—20 c.c. of the suspected milk are mixed with 1 c.c. of 50 per cent. potash solution, and heated in a bath of boiling water until the fat is saponified, when the solution turns yellowish brown. By this treatment the casein and albumen become soluble in acid. Twenty cubic centimetres of acetic acid are added, the solution shaken, heated on water-bath for three minutes, transferred to a strong glass tube, and turned in the centrifugal machine for ten minutes. The liquid is poured off, and the sediment is washed by shaking with 30 c.c. hot water, and again turned in the centrifugal machine. The water is poured off, and the sediment placed upon cover-glasses, which are treated in the ordinary way.

staining with hot Neelsen's solution, decolourizing in 25 p.c. sulphuric acid, and finally staining in methylene blue, instead of washing the cover-glasses in sulphuric acid Thörner simply uses a solution of methylene blue containing sulphuric acid

A METHOD of producing an intense monochromatic light is described by Dr Du Bois (*Zeitschr. für Instr.* p. 165). It differs from the usual processes in the form in which the sodium is introduced into the flame. A mixture of sodium bromide and bicarbonate is made cohesive by adraganth and moulded into sticks 4 mm. in diameter and 12 to 15 cm. long. These are kept in the flame of a Linnemann burner by means of a rack and pinion motion. Their conductivity being very low, they are only vaporized at the extreme end. The latter must be covered to avoid a continuous spectrum. At the greatest intensity, two or three centimetres of the substance are consumed per minute. The spectrum exhibits, besides the enormously preponderating D lines, a pair of lines in the green, and a fainter pair in the red.

FROM the ages of persons who have died in France during the last 32 years, M. Turquan computes the average life there to have been about 38 years for women, 36 for men, and 37 years for both sexes together (*Rev. Sci.*). But this is now exceeded, and the average is over 40 years, a result, partly, of more attention to hygiene, partly of a diminished birth-rate. From a map showing the distribution of the average life, one finds the average very low in Finistère and Brittany (28 years 11 months in the former) in the Nord, the Pyrénées Orientales, &c., and especially in Corsica (28 years 1 month). In Finistère and Corsica one finds least hygiene and most children, but not the highest mortality of children. In some parts of Normandy, with a high infantile mortality, the mean life is yet very long. Thus it is about 48 years in Eure, 47 in Orne and Calvados, &c. The difference between the average life of men and women rises to 4 years (excess in case of women) in the north-west, and diminishes as you come towards the Mediterranean, and in Basses Alpes and Gard (in the south-east) man lives longer than woman by about a year and a half. In Normandy and Brittany there are most widows, and woman appears to have a greater vitality.

IT is now many years since electric currents were proved to exist in plants. In the study of these currents, an important step in advance was taken when Prof. Burdon Sanderson proved their existence in *uninjured* parts of living plants (it was usual before to apply electrodes, often polarizable, to cut parts). As to their cause, certain experiments made by Kunkel, some time ago, led him to think it was in the purely mechanical process of water-motion, set up on application of the moist electrode. The subject has been recently investigated by Herr Haake, who pronounces against this view. He used Du Bois Reymond's clay electrodes, with some woollen fibres projecting at the ends, and he enclosed the leaves in a tube in which they were guarded from air-draughts and kept moist. Arrangements were also made for various operations, such as varying transpiration, admitting hydrogen, removing oxygen, &c. (for details see *Flora*, p. 455, of this year). Herr Haake's results are briefly these—1. It is unquestionable that changes of matter of various kinds are concerned in the production of the electric currents, especially oxygen respiration, and carbonic-acid assimilation. 2. Water-movements may possibly share in their production, but certainly their share is but a small one.

\*THE *Investia* of the East Siberian Geographical Society (vol. xxiii, 3) contains an account of M. Obrutcheff's further researches in the Olekma and Vitim highlands. In the north-eastern, formerly quite unknown part of this region, the author found a further continuation of the "Patom plateau"—

that is, a swelling from 3500 to 4000 feet high, devoid of tree vegetation, with ridges and mountains rising over it to heights of from 5000 to 5600 feet. They consist of granite and crystalline schists, probably of Laurentian age, covered with younger, probably Huronian, gneisses and schists. The other parts of the highlands consist of Cambrian and Lower Silurian deposits, while Upper Silurian limestones and Devonian Red sandstones are only met with in the valley of the Lena. We thus have a further confirmation of the hypothesis, according to which the great plateau of north-eastern Asia is a remnant of an old continent which has not been submerged since the Devonian epoch. Further traces of mighty glaciation have been found in the south-east part of the region. As to the gold-bearing deposits, they are pre-glacial in the south, and post-glacial or recent in the north. The high terraces in the valleys are indicative of a considerable post-pliocene accumulation of alluvial deposits, and of a subsequent denudation on a great scale.

Messrs. Macmillan and Co. announce that a new edition of Sir Archibald Geikie's "Text-book of Geology" is in the press, and will appear shortly.

THE third and fourth volumes (completing the work) of Mr. H. C. Burdett's "Hospitals and Asylums of the World" will be published by Messrs. J. and A. Churchill about the end of this month. Vol. iii. deals with the history and administration of hospitals in all countries throughout the world. Vol. iv. relates to hospital construction, and contains a bibliography and portfolio of plans.

Messrs. R. Sutton and Co. have published a second edition of Mr. J. E. Gore's "Scenery of the Heavens," with stellar photographs and various drawings. Mr. W. F. Denning contributes to the volume a chapter on fireballs, shooting stars, and meteors.

THE second annual issue of "The Year-Book of Science," edited by Prof. Bonney, F.R.S., is now in a forward state of preparation, and will be shortly published by Messrs. Cassell and Company.

Messrs. Dulau and Co. have published "Annals of British Geology, 1891," by J. F. Blake. This is the second issue, and geologists will be unanimously of opinion that it is a decided improvement upon the first. It contains a digest of the books and papers published during the year, with occasional notes.

LECTURES on the ear will be delivered in Gresham College, Basinghall Street, E.C., on January 17, 18, 19, and 20, at 6 o'clock, by Dr. E. Symes Thompson.

IN Mr. R. Asheton's letter (*NATURE*, vol. xlvii, p. 176) the sentence beginning line 31 of the second column should have read thus.—"But it is more metazoic—if I may use such a word—to call the whole animal resulting from the segmentation of the fertilized ovum, the sexually produced generation."

Two interesting new compounds are described by Prof. Anschütz, of Bonn, in the current number of the *Berichte*. They are well-crystallized compounds of the lactides derived from salicylic acid and the next higher (cresotinic) acid with chloroform, which latter substance is so loosely united with the lactide that warming to the temperature of boiling water is amply sufficient to dissociate them. Hence the compounds may be employed for obtaining perfectly pure chloroform, and for preserving chloroform in a solid form in which it is not prone to decomposition. The lactide of salicylic acid has long been supposed to be formed when the acid is treated with oxychloride of phosphorus. Prof. Anschütz, however, shows that the product of this reaction contains many other substances in addition, but by working under special conditions he has succeeded in

isolating pure salicylide Salicylic acid is dissolved in an indifferent solvent, preferably toluene or xylene, before the addition of the phosphorus oxychloride. The product of the reaction is washed first with soda and afterwards with water. Owing to the property, discovered by Prof. Anschütz during the course of the work, which salicylide possesses of combining with chloroform, it may be extracted from the white solid product, after drying, by means of chloroform, the compound being deposited from the chloroform solution in large colourless transparent crystals belonging to the tetragonal system. The compound possesses the composition  $C_6H_4COO \cdot 2CHCl_3$ . The chloroform readily escapes upon warming, in very much the same manner as the water of crystallization contained in many crystallized salts. The free salicylide remaining is a solid substance melting at  $261^\circ$ . As regards its molecular constitution it is shown, by the amount of lowering of the melting-point of phenol employed as a solvent, to contain four of the salicylic radicals  $C_6H_4COO$ , and is probably a closed ring compound. In a precisely similar manner phosphorus oxychloride reacts with the three cresotinic acids, the acids next higher than salicylic, with formation among other substances of lactides, which may be isolated in the same way in the form of their chloroform compounds,  $CH_3C_6H_3COO \cdot 2CHCl_3$ . Ortho-cresotinic acid lends itself best to this reaction. The pure lactides are readily obtained from the chloroform compounds by warming to  $100^\circ$ , pure chloroform being gently evolved.

THE two substances above described, salicylide chloroform and the corresponding compound derived from ortho-cresotinic acid, are admirably adapted for the preparation of pure chloroform, on account of their large content of the latter substance, salicylide-chloroform containing 33.24 per cent and the cresotinic compound 30.8 per cent of its weight. Moreover, in closed vessels they may be preserved any length of time, when exposed to the open air salicylide chloroform slowly loses its chloroform, but the cresotinic compound is well nigh stable, even under these conditions. The same quantity of the free lactide may be used over and over again without decomposition, it being only necessary, in order to re-form the chloroform compound, to allow it to remain in contact with the chloroform to be purified for twenty-four hours at the ordinary temperature. None of the usual impurities in chloroform crystallize along with the compound, so that a perfect separation is effected. Again, it is well known that pure chloroform decomposes more or less on keeping, this loss may be avoided by storing it in the form of the lactide, and regenerating it when required by the application of a gentle heat, with the certainty of obtaining it perfectly pure.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* 9) from India, presented by Mr. W. Stutely, two Barbary Mice (*Mus barbarus*) from North Africa, presented by Lord Lilford, four Bearded Titmice (*Panurus biarmicus*), European, four Ani (*Crotophaga ani*) from South America; six Hog-nosed Snakes (*Heterodon platyrhynchos*), a Striped Snake (*Tropidonotus striatilis*); a Snake (*Pituophis* —), from North America, purchased.

### OUR ASTRONOMICAL COLUMN

THE MOTION OF NOVA AURIGÆ — Prof. W. W. Campbell, of the Lick Observatory, has communicated further results relating to Nova Aurigæ to the December number of *Astronomy and Astrophysics*. He is now perfectly convinced that the variation in the velocity previously suspected is real, and probably due to orbital motion. The values given below have been calculated on the assumption that the brightest line in the spectrum of the Nova, since the reappearance in August, is

really the chief nebula line. The bright lines were displaced towards the violet, indicating approach, whereas in February and March last they were displaced towards the red.

Date 1892	$\lambda$	Velocity of approach Miles per sec
Aug 20	5003.6	128
21	3.7	125
22	3.7	125
23	3.1	147
30	2.4	173
Sep 3	2.4	173
4	1.9	192
6	2.1	184
7	1.9	192
15	2.2	180
22	2.5	169
Oct 12	3.6	128
19	3.8	121
Nov 2	4.4	99
3	4.7	87

In the same journal Mr. Sidgreaves points out that the new lines cannot simply be revivals of those of February, and, further, that on account of the great difference of velocities and the reversed direction, they cannot be supposed to belong to the bright-line component of February. Neither is it likely that the dark-line component has become a planetary nebula, and the probability of three bodies rushing together being very small, Father Sidgreaves believes the new results to strengthen the view that the compound character of the spectrum was produced by local disturbances of a single star.

ASTRONOMICAL DISCOVERIES IN 1892 — In the *Observatory* for January Mr. Denning gives an excellent summary of the astronomical discoveries of 1892, a year which was very remarkable for the special attention given to the science by the press and the public. In chronological order the principal events were as follows —

January 20 — Minor planet (324) discovered by photography by Max Wolf at Heidelberg. (Altogether 27 were discovered during the year by various observers.)

January 23-30 — Discovery of Nova Aurigæ by Dr. Anderson.

February 11 — The great sun spot, extending over 150,000 miles of longitude, reached the sun's central meridian. This was followed by remarkable magnetic disturbances and displays of aurora.

March 6 — Comet discovered by Lewis Swift.

March 18 — Comet discovered by Denning at Bristol. On this day also, Dr. Spitaler, of Vienna, re-detected the periodical comet of Pons (1819) and Winnecke (1858).

August 6 — Opposition of Mars. Mr. Denning writes: "Practically our knowledge stands where it stood before. The results are not sufficiently discordant to settle disputed points."

August 27 — A new comet discovered by Brooks, of Geneva, N. Y.

September 9 — Prof. Barnard's memorable discovery of the fifth satellite of Jupiter.

October 12 — Comet discovered by photography by Prof. Barnard.

November 6 — Bright comet discovered in Andromeda by Mr. Edwin Holmes, London.

November 20 — A faint comet discovered by Brooks.

November 23 — Brilliant shower of shooting stars observed in Canada and the United States. The shower was evidently that of the Andromedes connected with Biela's comet.

COMET HOLMES — Mr. Lewis Boss finds for this comet a period of 6914 years, and concludes that no very close approach to Jupiter can have taken place in recent years; the eccentricity, however, is so small that important perturbations by Jupiter may have occurred. He further states that "the recent remarkable decrease in brightness of the comet seems to do away with the necessity of supposing that it has been recently made a member of the solar system. This decrease also renders it reasonably certain that the comet must have been subjected to some extraordinary disturbance of its internal economy, by the application of forces from without or within, with the result of giving to it that which was really an unaccustomed and temporary size and brightness" (*Astronomical Journal*, No. 283). According to Mr. Lockyer's views, such increase of brightness would be produced by the comet colliding with another meteor.

swarm lying in its track, and it is quite possible that the brightening of the comet at the time of the discovery was very sudden, thus explaining why the comet was not detected earlier.

The Rev E M Searle (*Astronomical Journal*, No 283) has deduced a period fifteen days shorter than that of Mr Boss.

M Schulhof, of Paris, finds a period of 6909 years. He also points out that among the known periodic comets that of De Vico shows the greatest orbital similarity to Holmes's comet, and he considers that they may possibly have a common origin.

Mr Roberts, of the Nautical Almanac Office, accepting as real the supposed impression of the comet obtained by Mr Schorling in a photograph of the region taken on October 18, found a period of fifteen years, but the general agreement of the latest computations seems to indicate that the image in question could not be that of the comet.

The comet is now so dim that it is not considered necessary to continue the ephemeris.

EPHEMERIS OF COMET BROOKS (November 20, 1892) —The following ephemeris of Comet Brooks (Berlin, midnight) is given in *Ast. Nach.*, No 3140, by Kreutz —

Date	R.A. h m s	Decl. (app) ° ' "	Log $r$	Log $\Delta$
Jan 12	21 40 18	+ 59 41	0 0786	9 8915
13	56 4	58 8 1	0 0791	9 9012
14	22 9 53	56 33 6	0 0797	9 9114
15	22 3	54 59 1	0 0803	9 9220
16	32 47	53 25 7	0 0810	9 9330
17	42 18	51 54 2	0 0818	9 9442
18	50 47	50 25 2	0 0826	9 9556
19	22 58 23	48 59 3	0 0835	9 9670

THE METEOR SHOWER OF NOVEMBER 23, 1892 —Further observations of this fine display of shooting stars are recorded in *Astronomical Journal*, No 283. Prof J K. Rees counted 165 meteors in half an hour, and noted some as bright as Mars, all of them were very swift. The Rev J G Hagen estimated that one observer, with a clear view to the west would have seen 250 meteors in half an hour, and notes that some were as bright as Jupiter. Mr Sawyer estimated the maximum frequency as about 300 per hour, and, strangely enough, describes them as "slow-moving, generally quite bright, although none were observed as bright as the planets Mars and Jupiter." Both Prof Rees and Mr Sawyer note that the meteors appeared in clusters, four or five falling almost at the same instant, while for a few minutes none were seen. The radiant was near  $\gamma$  Andromede, and there is little doubt that the shower was that due to Biela's comet.

### GEOGRAPHICAL NOTES

IN M Dybowski's journey from the Mobangi to the Shari, as described at a recent meeting of the Paris Geographical Society, he encountered one of the most systematically cannibal tribes which has yet been described. This tribe, known as the Bonjos, have only one object of purchase—slaves to be eaten. They refuse to sell food or any other products of their country for anything else, and the surrounding tribes capture and export canals of slaves for this purpose. The French expedition experienced great difficulty in obtaining food amongst a people who had no desire for ordinary articles of trade.

THE boundaries of the republics of South and Central America are certainly the least definite lines on the political map of the world so far as civilized lands are concerned. The question of delimitation is never at rest. Dr. H. Polakowsky gives in the last number of *Petermann's Mitteilungen* a brief account of the negotiations and surveys relating to the frontier of Costa Rica and Nicaragua from 1858 to 1890. The difficulty in this case lies in the fact that the mouth of the San Juan river, a certain point of which was fixed on in 1858 as the coast frontier, is continually changing, and a breakwater belonging to the harbour and canal entrance of Greytown, in Nicaragua, now stands in what was formerly the territory of Costa Rica. On the Pacific coast years of diplomacy were required to fix the centre of Salinas Bay, but it is satisfactory to know that permanent boundary stones have now been erected at both ends of the line.

MR. COLLS delivered his second lecture to young people under the auspices of the Royal Geographical Society, on

NO. 1211, VOL. 47]

Friday evening, when a large audience of both young and old enjoyed his spirited descriptions of Iceland and British Columbia, illuminated by many anecdotes of personal adventure.

THE defective condition of the charts, even of the coast of Europe, was strikingly brought out by the recent court martial on the stranding of H M S *Howe* in Ferrol Channel. The chart used on board was drawn from soundings made about a hundred years ago, with a few subsequent corrections, which failed altogether to indicate the rock on which the *Howe* struck. The Spanish authorities are reported to have refused permission for the new chart surveyed by the officers of the Channel Squadron to be published, and meanwhile the Hydrographic Office has cancelled the old chart.

### A NEW SEISMOGRAPH

BEFORE speaking of this memoir, let me enter a protest against the method of publishing these "Annali" in such a way as to convey the impression that the papers composing it were written three years before their actual date. All readers are warned that when the volume is bound up, and the paper covers are removed, they must post date the papers by three years.

The seismograph described in the present paper is intended for stations of the second class. The objects in view in its construction were amplification of the record in a pendulum seismograph, and improvement of the warning apparatus in the form of a style seismoscope of the Milne type which the author finds frequently fails.

The amplifying lever is composed of fine placfont tubes arranged girder-like in the form of a short hollow triangular prism, surmounted by an acute triangular pyramid, which points downwards, and carries at its apex the writing style. The pendulum bob is a flattened cylinder, supported by a placfont wire 150 m long. The amplifying lever at the junction of the three pyramidal and the prismatic tubes supports three radial arms meeting in the centre, as it were, of the pyramid base, and support a ball-and-socket joint of agate, the cup part of which is at the end of an arm projecting from the supporting wall. Immediately above this centre, and occupying the prism space of the lever, is the cylindrical box, the wire supporting which passes through a small hole in the centre of the base of the prism. We thus have a simple lever of the first order of light girder work. It is prevented from rotating in azimuth by including some steel wire permanently magnetized.

The style has been modified by lightening it and making it more rigid and non oxidizable, which is done by using a capillary glass tube.

The registering apparatus is a smoked glass plate, supported over a clock, started at the moment of the earthquake by a seismoscope. To prevent the complex figures of the ordinary registration in a pendulum seismograph, the author has arranged so that the plate shall rotate through a segment of a circle every three seconds, so as to bring a fresh surface of smoked glass beneath the style.

Some modifications are then described. The principal one is making the bob annular, carrying a suitable aperture, in which is engaged the short end of a lever. This lever is composed of three very thin brass tubes, graduating away smaller from the fulcrum, which is a gimbal joint such as suggested by the reviewer some years since in *NATURE*. This lever carries at its lower and longer end the style which records on the glass plate as in the original one described in this memoir.

Another modification is a combination of the triple and single suspension of the pendulum bob, that is, the bob ring is first suspended by triple wires to a button which in its turn hangs at the end of a single wire.

The details of these seismographs are fairly well worked out, but the employment of aluminium in many of the parts has been neglected. Likewise, no arrangement has been made for the oblique play of the engaged union in the newer lever. The only new point about this seismograph is the interrupted rotation of the recording plate. This has a decided advantage in giving a dissected record, but is partly counterbalanced by the fact that important movements that may be taking place at the moment

<sup>1</sup> G. Agamennone, "Sopra un Nuovo Pendolo Sismografico" *Annali dell' Ufficio Centrale Meteor. e Geodinamico*, ser. sec. pt. 3, vol. xl., 1890. (Roma, 1890.)

of the advance are represented by a curve or curves which would require a series of careful experiments to be carried out in each instrument, followed by difficult and elaborate calculation for each advance.

Much credit is due to the author for working out the modifications, but until we have some original method of finding a steady-point, not so far suggested, it is doubtful if we can improve on the Gray, Ewing, and Milne seismographs, that are not, as the author imagines, little used or tested instruments.

H J JOHNSTON LAVIS

## PHYSICAL GEOGRAPHY AND CLIMATE OF NEW SOUTH WALES

A SECOND edition of an excellent pamphlet on the "Physical Geography and Climate of New South Wales," by Mr H C Russell, F R S, astronomer royal for New South Wales, has just been issued at Sydney. It is published by authority of the New South Wales Government. The following extracts may be of interest to various classes of readers in Great Britain—

Looking back through the pages of history, and the dim traditions of an earlier time, we find abundant evidence of a belief in the existence of a great south land to the south and east of what was then the well known earth. Those early navigators whose travels had fostered this belief, had doubtless followed down the Malay Peninsula and the string of islands which seem to form part of it, in search of spices and other treasures which the islands supplied. Pliny, who had evidently gathered up the traditions of "Terra Australis incognita," says that it lay a long way south of the Equator, and in proof of this mentions the fact, strange in those days, that when some of its inhabitants were brought to civilization they were astonished to find the sun rise on their left hand instead of on their right. And Ptolemy, A D 170, after describing the Malay Peninsula, says: "Beyond it, to the south-east, there was a great bay in which was found the most distant point of the earth, it is called 'Cattigara,' and is in latitude  $8\frac{1}{2}^{\circ}$  south," "thence (he goes on to say) the land turns to the west, and extends an immense distance until (as he believed) it joins Africa." And it may fairly be assumed that the extreme south latitude of Cattigara, and its situation in a great bay where the land turns to the west until it joins Africa, is proof that it was some point in the Gulf of Carpentaria, for no other place would fulfil the conditions. The idea that the land actually reached Africa was not Ptolemy's, it was a necessary part of the system of Hipparchus, for he taught that the earth surrounded the water and prevented it from flowing away. It is not surprising, therefore, that the early navigators, following down the islands, came at length to that part of the Gulf of Carpentaria where the land turned to the west, and believing Hipparchus' system of geography, thought that in turning to the west they were in reality turning towards home, and Cattigara was therefore the most distant point known. Marco Polo tells us that the Chinese navigators in his day (A D 1293) asserted there were thousands of islands in the sea to south of them, and in the present day we find proofs of their early visits to Australia in the traces of Chinese features amongst the natives of the northern coast, indeed, some historians think that Marco Polo, in the account he gives of the expedition sent to Persia by the Great Khan, refers directly to Australia, under the name of Lochac. This place he says was too far away to be subjugated by the Great Khan, and was seldom visited, but it yielded gold in surprising quantity, and amongst other wonders contained within it an immense lake or inland sea. It is impossible that such a description should apply, as has been thought, to the Malay Peninsula,—a country within easy reach, and one which his ships must have passed in every voyage, and so far from being beyond his power, it was within the limits over which his sway extended. That Lochac formed part of the main land was also quite in accordance with their ideas of the earth, which surrounded the ocean, and the abundance of gold is certainly more likely to be true of Australia than of the Malay Peninsula.

For long years after Marco Polo we find no direct reference to Australia, except the stories which lived amongst navigators, and seemed to lose none of their marvellous points by transmission. These kept alive the desire to explore the great south land, so rich in treasures and wonders. All the evidence collected so far goes to prove that the Portuguese had, early in the

sixteenth century, explored at least the northern parts of Australia. What they learned was, however, kept a profound secret until about 1540, when one of their government maps was stolen, and there are now in existence six maps believed to be copies of it, which were all published between 1539 and 1555. These all show Australia under the name of the "Land of Java," the real Java being called the "Little Java," and from this time onward frequent attempts were made to explore what had for so many generations been "Terra Australis incognita." Sturdy navigators could not understand the silence of the Portuguese, except as proof of the richness of the land, about which tradition told wonderful tales. "It was a land of gold and spices, of magnificent tropical fruits and vegetation—a perfect paradise, in which the happy and simple inhabitants were loaded with jingling ornaments of gold. Its very atmosphere was elixir, and existence a round of enjoyment." No wonder that in an age when, at least upon the ocean, the power to take was mistaken for the right to do so, there were many who cast longing glances towards the southern Paradise. Whether these stories of gold had any foundation in fact or not, when barter was regularly exchanged on the coast of Australia, it is impossible now to say, but more recent discoveries of rich surface gold lend some colour to them, and the vegetable richness of the northern part of Australia is quite in accordance with tradition. But all the early English navigators were unfortunate, and Australia got a reputation the very reverse of what further investigation has shown that it deserves. In point of fact, all the glowing colouring of tradition is true, but when Dampier, in 1688, sailed down the western coast, he saw nothing but a "dry sandy soil," and the "miserablest people in the world," and later on, when the first English settlers landed on Australia, they chose a bay, beautiful to look at, but there was no gold and no fruit worthy of the name, the soil was barren and sandy, and the climate in the worst part of its summer. No wonder that the fame of Australia was blackened, and report made it a miserable land, subject to droughts and floods—a land in which everything was turned topsy-turvy. The summer came at winter time, trees shed their bark, not their leaves—were brown instead of green, the stones were on the outside of the cherries, and the pears, pleasant to look at, were only to be cut with an axe, and there was nothing to eat, "unless, perchance, ye'll fill ye with root of fern or stalk of lily." Such was the early verdict upon Australia. Fortunately the first colonists, once here, were obliged to stop. By degrees they found that everything that was planted grew well, that wheat in the valley of the Hawkesbury yielded 40 to 50 bushels to the acre, and in one memorable season actually ruined the farmers by its very abundance, for in the then limited market, the price fell so low that it was not worth gathering, and it was left in the fields to rot, while the farmers sought other work. Horses, sheep, cattle, and pigs thrived marvellously, and some of the cows getting away, the bush soon contained numbers of wild cattle. Even wool did not deteriorate in the new Colony, and step by step the facts became too strong for prejudice, and the first fleeces of Australian sheep sent to England lifted the veil. Manufacturers would gladly take as many as could be sent, their demand for more wool extends with the supply, and now only from Australia can they obtain the fine wools which they need. Quantity and quality of wool have increased together, and the Grand Prize at the Paris Exhibition for our New South Wales wool has proclaimed the fact far and wide. Wool has done still more for the Colony. We took possession of it as a narrow strip of coast country, the demand for pasture forced us to find a way over a hitherto impassable range, and the same want has driven all the desert out of the Colony, and covered it with sixty two millions of valuable sheep (1892). The country which early writers upon Australia called a barren waterless desert is now growing the finest wool and yielding abundant water from wells, and when, in 1851, it was announced that gold had been discovered in abundance, the world was convinced that Australia was a promising country after all. Year by year the people have been coming in increasing numbers to supply our great want (population), and as our numbers increase new avenues of wealth and prosperity are opening before us.

Geographically, Australia has a grand position, lying between the 10th and 40th degrees of south latitude—that happy mean where it is neither too hot nor too cold. Surrounded by the ocean, the sea breezes temper what might otherwise be a hot climate in the summer, the air is clear and dry, and yet brings rain in heavy showers. Vegetation is abundant, and includes

all the cereals and fruits of the world, so that, in the words of the old tradition, it has "all the conditions which make life a pleasure."

Australia measures from north to south 1900 miles, and from east to west 2400 miles, and speaking generally, has a rounded outline, the only great inlets on the coast line being the Gulf of Carpentaria and the Australian Bight. The total area is rather greater than that of the United States, and almost equal to the whole of Europe. On the east, north, and west, and at a short distance from the coast are found ranges of mountains, of no great elevation, yet almost the only high land. On the west and north-west coasts the mountains form a bold outline of granite, rarely more than 200 miles from the coast, and attaining to heights of 2000 to 3000 feet. Between these and the sea the land is low and good, but on the inland side is found a vast table land which slopes towards the unknown interior so gradually that the inclination is not easily seen, and no rivers running to the interior have yet been discovered—all known streams running to the sea.

On the east coast we have also the mountain chain parallel to the coast, but it is much higher and more extensive, and the strip of low land by the coast is much narrower, often not more than 30 miles wide, and at Point Danger the range comes right to the sea. This grand chain of mountains is known generally as the Great Dividing Range, and extends for about 1500 miles along the east coast. Near its southern extremity is the Snowy Range, the only spot in Australia where snow may always be found. The highest peak, Mount Kosciusko, 7170 feet, is also the highest land in Australia. The ravines on its sides always contain snow, and the mountains near it, about 6000 feet high, are also covered with snow for the greater part of the year.

Of this great continent island, the Colony of New South Wales holds the choicest portion—the southern part of the east coast—the part where, with remarkable sagacity, the first settlement was made. It has the best climate, all the most important rivers in Australia, the great bulk of the coal land, unlimited stores of all the useful minerals, and the finest pastoral and agricultural lands for extra-tropical vegetation, besides which, its extensive highlands afford climatic conditions for all purposes. It is naturally divided into three portions. The comparatively narrow coast district, from 30 to 150 miles wide, abundantly watered by rivers and smaller streams coming down from the mountains. The rainfall here, fed by winds from the Great Pacific Ocean, is very abundant, from 40 inches in the south to 70 in the north, and at Sydney 50 inches. The mountains have doubtless very much to do with this abundant precipitation, and at times the rains are so heavy that the rivers, fed by mountain torrents, carry heavy and dangerous floods. In years past wheat was largely and profitably grown, but rust has of late so frequently appeared that little or no wheat is grown, for it pays better to supply the city markets with dairy produce, Indian corn, and various kinds of hay. In the northern districts sugar-growing is a profitable industry, and increasing rapidly. About Sydney enormous quantities of oranges are grown for exportation.

The second division includes the mountains and elevated plains, and extends the whole length of the colony, varying in width from 120 to 200 miles. On the south, with the exception of the Monaro Tableland, the country is very rough and mountainous, the highest points, Mount Kosciusko and the Snowy Range, catch the rain and snow that feed the river Murray and the Murrumbidgee. Wheat grows well here, but nearly all the land is used for pastoral purposes. Proceeding northwards, the mountains decrease in height and extend laterally. A part of the land is taken up for agriculture, some for mining. In its natural state the western country is open plain or lightly-timbered, and large areas are covered with rich volcanic soil which seems fit to grow anything, but the want of labour and carriage, and the profit and security to be found in raising wool and meat, has for the most part tempted capital into squatting pursuits, but since the railway has reached this part of the country more attention is being given to agriculture, and it is rapidly extending. Between Goulburn and Bathurst, the western waters form the Lachlan and the eastern the Hawkesbury rivers, and from Bathurst northwards to latitude 25° all the western waters go to form the various tributaries of the Darling river. These mountains are from 2000 to 3000 feet, with some peaks rising to nearly 6000 feet. The central parts of the western slopes are celebrated for rich soil and

herbage, and here also the greater part of the gold mining area, as well as mines for other minerals have been found, including coal, which is also found in great abundance, with iron and lime, at Lithgow and other places. Deposits of copper, silver, lead, tin, and mercury are also found in abundance. A very large portion of the high land here is suitable for agriculture, and is being taken up for that purpose by degrees. English fruits—the apple, cherry, currant, &c—grow to perfection here, as well as in other parts of the mountain districts.

The third division covers by far the greatest area, and consists of the Great Western Plains, extending away to the Darling river, and thence to the south Australian border. Here there are but few known mineral deposits except copper, and the enormous deposits of silver and lead at Broken Hill, and no attempt at agriculture. All the land may be said to be held for grazing purposes, and for that purpose, now that capital has been invested in tanks and wells for water supply, this country is unequalled. Sheep and cattle thrive in a remarkable degree, and form a most profitable investment, the climate being dry and wonderfully healthy for man and beast.

These are the three great natural divisions, made so by the conformation of the land and the climate. It will be evident from what has been said of the elevation of the mountains that snow is not a common feature upon them, and the only part where snow lies for any considerable time is the extreme south. As a necessary consequence, the river system is peculiar; indeed, it has often been asserted that Australia had no rivers—at least none which were of any use as such, but as we shall presently see, this statement, like many others affecting Australia, was made in ignorance. The necessity for increased pasture had driven the early colonists to cross the Great Dividing Range, aptly so named, in search of pasture, in 1815, and the desire to extend the new pastures beyond the Bathurst Plains, which were the first discovered, led them on, and one of the first questions that demanded their attention was to account for the direction in which all the streams were flowing. The shortest road to the sea was to south-west, and yet all the water was running to north-west, and quite naturally it was asked—Could there be a great inland sea into which these rivers discharged? In 1818 Oxley started with a determination to see where at least one of them went to; so he followed the Macquarie for more than 200 miles, and found that he was going due north-west, further and further, as it seemed to him, from the natural outlet on the south coast. At last the river spread out to an apparently interminable marsh. Turn which way he would his progress was stopped by a shallow fresh-water sea, for sea he was at last convinced it must be, so great was its extent, and he was obliged to turn back. He had got there after two very wet seasons (1817 and 1818), and his inland sea is now known as the Macquarie Marshes, and the mystery was not solved until Sturt, in 1829, found all these streams trending to north-west unite in the Darling, and then turn to south-west.

Coming from mountains of such moderate elevation, these streams are necessarily dependent upon the rainfall, and have no snow to help them, so that in rainy seasons they become important rivers and in dry ones sink into insignificance, but since most of the rains which feed these waters are, as it were, offshoots of the tropical rains, they seldom fail altogether, and as a rule the Darling is navigable for four months of each year, and sometimes all through the year, up to and beyond Bourke. The current is very slow, seldom reaching two miles per hour, and therefore offers little hindrance to the steamers which carry wool and stores.

In the exploration of our rivers there was another surprise when settlement extended south-west from Sydney. The waters here were found to flow to the west, and the Lachlan has for a considerable portion of its course a south-west direction, that is, at right-angles to the Macquarie and the Bogan. Could the Lachlan, the Murrumbidgee, and the snow-fed Murray ultimately join the waters that ran north-west from Bathurst? Sturt had not solved this question—he only followed the Darling part of the way down—and it was left for Sir Thomas Mitchell to find the junction of the two river systems in 1835, and to prove that the Darling and the Murray were united at and below Wentworth.

After dealing with the rivers and harbours of New South Wales, Mr. Russell discusses the temperature, rainfall, droughts, and winds of the colony. Of the temperature he says—

In works of reference, Australia generally is credited with heat in excess of that due to its latitude. It is difficult to say why, unless it arose from a habit of one of our early explorers who carried a thermometer and carefully published all the high, and none of the low readings he got, until, fortunately for the colony, the thermometer was broken and the unfair register stopped. But not only the interior—Sydney even to the present day is credited, in standard works of reference, with a mean temperature of 66° 2', or more than three degrees higher than the true mean, which is 62° 9'. Such an error is not excusable when meteorological observations have been taken and published for just forty years. There is another error made by some writers when describing Australia. It is shown by them inverted on the corresponding latitudes in Europe, and the reader naturally infers that Australia is as hot as those parts of Europe. Confining our attention to New South Wales, that is between 29° and 37° of south latitude, we find that generally it is cooler than a corresponding part of Europe. The mean temperature of the southern parts of England is about 52°, and that of France, near Paris, about the same, increasing as you go south to 58° 5' at Marseilles. Taking this as a sample of the best part of Europe, let us see how the mean temperatures in the colony compare with those. Kiandra, our coldest township, situated on a mountain, is 46°. Cooma, on the high land, 54°. Queanbeyan, high land, 58°. Goulburn, high land, 56°. Armidale and New England district, 56°. Moss Vale, 56°. Kurralong, 53°. Orange, 55°. These towns are scattered along the high table lands from south to north, and represent fairly the climate of a very considerable portion of the whole colony. Next to this in point of temperature is the strip of land between the ocean and the mountains, and which is affected by the cooling sea-breezes. Here we have a mean temperature ranging from 60° at Eden, the most southern port, to 68° at Grafton, one of the northern ports. Sydney, in latitude 34°, has a summer temperature only four degrees warmer than Paris, which is in latitude 49°. Now the usual difference for a degree in latitude is a degree in temperature, and therefore, if Sydney were as much warmer than Paris as its latitude alone would lead us to expect, its temperature should be 74°, and that is 15° warmer than Paris, but as we have seen, it is only 4° warmer. This single example is enough to prove the comparative coolness of our coast districts. The investigation made during recent years shows that the mean temperature of the whole colony, as derived from forty-five stations scattered over it, is 59° 5', three degrees lower than that of Sydney, or only one degree hotter than that of Paris.

It may be mentioned that the highest shade temperature ever recorded in Sydney was 106° 9', and near Paris a temperature of 106° 5' has been recorded.

The third great district, consisting of lower land and plains to the west of the mountains, has a climate considerably warmer in summer than the parts above described, owing to the powerful effect of the sun on land having little forest and little or no wind; but in winter the temperature sinks down much lower than the coast districts, owing to the great radiation, so that the annual mean temperature is not so great as the summer heats would lead one to anticipate. A table has been prepared for the purpose of showing by comparison with many places in Europe and America the temperature of the colony. The places have been arranged in order of temperature, taking for that purpose the mean annual temperature. This shows at once that the range of temperature here is equivalent to that offered by Europe from the north of England through France to Sicily. Such a range is more remarkable, because if New South Wales were placed on the map of Europe according to its latitude it would extend from Sicily to Cairo, whereas when placed by its temperature it stretches as we have seen from Sicily northwards to England. Nor is this all that the table shows us. For even when we find a place in Europe with a temperature equal to that of some place here, it is at once observed that the summer temperature in Europe is warmer than the colonial one and the winter colder, for instance, Naples, 60° 3', Eden, 60° 3', summer at Naples, 74° 4'; at Eden, 67° 9', winter at Naples, 47° 6', Eden, 51° 9'; and so generally the southern country has the cooler and more uniform temperature. It is worthy of remark that the only places here of equal mean and summer temperature with places in Europe are those which are to be found on the western plains, as at Wagga Wagga, which has a mean temperature of 60° 3'; Naples, 60° 3'; and summer temperature of both is 74°; or again, to compare the places of the

same or nearly the same latitude, Messina, in Sicily, latitude 38° 11', has a mean temperature of 66°, summer 72° 2', winter 55°; Eden, New South Wales, in latitude 37°, has a mean temperature of 60° 3', summer 67° 9', winter 51° 9', or Cairo, in latitude 30°, mean of 72°, summer 85° 1', winter 58° 2', Grafton, latitude 29° 45', mean 68° 1', summer 76° 8', winter 58° 4'. It is useless to multiply examples,—we have here enough to show how much cooler Australia really is than the fervid imaginations of some writers have made it appear in print.

Looking at this question of temperature generally, it will be seen that New South Wales is no exception to the general deduction of science that the southern lands are cooler than those of corresponding latitudes in the north, and it is only during hot winds, which are very rare in New South Wales, that the temperature rises to extremes. But to leave Europe, and compare the climate of New South Wales with that of America. Our limits of latitude would place us from Washington to New Orleans. Now the mean temperature at Washington is 55° and at New Orleans 68°, while that of Eden is 60° 3' and Grafton 68° 1', so that if mean temperature were a complete test of climate it would appear that our coast is hotter than corresponding latitudes in America. But mean temperature is not enough, we must compare the summer and winter temperatures, and summer at Washington rises to 76° 7' and at Eden only to 67° 9', 9° cooler, New Orleans summer is 82° and Grafton 76° 8', but 82° hardly represents the summer heat at New Orleans, for it is a steady broil, during which every day for three months of summer the heat is over 80°, a temperature that is only reached on this coast during hot winds, or in other words, very seldom. But winter temperature at Washington falls to 37° 8', and at New Orleans to 56°, at Eden 51° 9', and at Grafton 58° 4'. Hence it is evident that on this coast the heat is very much less in summer and greater in winter than upon the coast of America. Such facts place the colony in a very different position in regard to climate from that which it has occupied in published works, for instead of being a hot country we see that its coast districts are much cooler than corresponding latitudes in Europe and America, and that in its elevated districts, which comprise a large part of it and much of the best land, it has a climate no warmer than the best and most enjoyable parts of Europe in much higher latitudes, but while bringing these facts into due prominence it is not the intention to deny that another considerable part of the colony, forming the western plains, is subject to greater heat, caused, no doubt, by the sun's great power on treeless plains, and the almost total absence of cooling winds, yet, although in summer the temperature here frequently rises over 100°, and sometimes up to 120°, yet, owing to the cold at night and in winter, the mean temperatures are not greater than those of corresponding latitudes in the northern hemisphere, and this part of the colony being remarkably dry, the great heat is by no means so enervating as a temperature of 80° in the moist atmosphere of the coast, and, what is of still more importance, it does not produce those terrible diseases which are usually the offspring of hot countries. This is also, no doubt, due to the dryness of the air. Stock of all kinds thrive remarkably well, and are very free from disease in those hot western districts.

## SCIENTIFIC SERIALS

THE *Quarterly Journal of Microscopical Science* for August 1892 contains.—On the anatomy of *Pentastomum teretissculum* (Baird), by Prof. W. Baldwin Spencer, M.A. (Plates I. to IX.). Whilst collecting on Kings Island, which lies to the west of Bass Straits, half-way between the mainland of Victoria and Tasmania, numerous specimens of the copper-head snake (*Hoplocephalus superbis*) were found, in the lungs of which a large species of *Pentastomum* were parasitic; afterwards the same parasite was discovered in the lungs of the black snake (*Pseudochelys porphyriacus*) in Victoria; on examination there seemed little doubt but that the species was the one described by Baird long ago (1862) from specimens obtained in the mouth of a dead copper-head snake in the Zoological Gardens, London, under the name of *Pent. teretissculum*. In this paper we have a very complete account of the anatomy of this form, there being descriptions and figures of its external anatomy, schematic

representations of the muscular, alimentary, secretory, nervous, and reproductive systems, and an account of the sense organs. The paper is illustrated by ten double plates.—On the minute structure of the gills of *Palamonetes varians*, by Edgar J. Allen, B Sc (Plate x) It would seem that so far as the gills of this crustacean are concerned, the statement made by Haeckel and Ray Lankester, that the circulatory system of the Decapoda is everywhere closed, does not hold true. It would also seem fairly certain that the masses of cells surrounding the venous channels, in which Kowalevsky found litmus deposited a few hours after its injection, exercise an excretory function. In addition to these excretory cells, a large number of glandular bodies occur in the axis of the gill, and these are of two kinds—clear and reticulate glands.

The number for November 1892 contains.—On the development of the optic nerve of vertebrates, and the choroidal fissure of embryonic life, by Richard Aasheton, M A (Plates xi and xii) That the optic nerve is formed by the differentiation of the cells of the optic stalk into nerve fibres, which consequently lose connection with the inner wall of the optic cup, and piercing the outer wall, make connection with the outer face thereof, is held to be probable by such writers as Balfour, Foster, Marshall, Haddon, and others, whilst the opinion that it is formed by the growth of nerve fibres either from the retina (outer wall of the optic cup) or from the brain, along the optic stalk, but outside it and unconnected with it, is or has been held by His, Müller, Kolliker, Hertwig, Orr, and has been recently supported by Keibel, Froniep, and Cajal. Schafer seems to be uncertain which view to take. As the result of the author's investigations in the frog and chick, he concludes that the optic stalk takes no part in the formation of the nervous parts of the organ of sight. The optic nerve is developed independently of the optic stalk, and at first entirely outside it. The great majority of the fibres forming the optic nerve arise as outgrowths from nerve cells in the retina.—On the larva of *Asterias vulgaris*, by George W. Field, M A (Plates xlii to xlv) —On the development of the genital organs, ovoid gland, axial and aboral sinuses in *Amphipura squamata*, together with some remarks on Ludwig's hæmal system in this ophiurid, by E. W. MacBride, B Sc (Plates xvi to xviii) Concludes that echinoderms agree with other coelomata in the origin of their genital cells these latter have at first an unsymmetrical position in echinoderms, and afterwards take on a radially symmetrical disposition in correspondence with the secondarily acquired radial form of the body. The origin of these cells adjacent to the stone canal suggests a comparison of the origin of the genital cells near the nephridia in many annelids, but the homology of the stone canal with a nephridium has yet to be proved.—On a new genus and species of aquatic Oligochaeta belonging to the family Rhinodrilidae, found in England by W. B. Benham, D Sc (Plates xix and xx) This new worm receives the name of *Sparganophilus famesis*, it was found in some numbers in the mud of the Thames, adhering to the roots of *Sparganium ramosum*, near Goring; the cocoon is drawn out to a point at one end, while in the other it shows a narrow frayed end. As the home of the Rhinodrilidae is America, the author suggests that the cocoons of this worm may have been introduced into the Thames amongst the roots of water plants, or attached to timber from the United States.

*American Meteorological Journal*, December.—Atmospheric electricity, earth currents, and terrestrial magnetism, by Prof. C. Abbe. The author has collected from various telegraph companies particulars about electrical storms, which illustrate the magnitude of the disturbances that frequently occur. The present electrical and magnetic observatories, which usually observe only some part of the whole series of phenomena, need to be supplemented by completely equipped establishments recording continuously the north-south, the east-west, and the zenith-antipodal differences of potential. The ordinary records of atmospheric electricity give merely the difference of potential of the earth and a point in the atmosphere defined as the end of the water-dropping collector.—Notes on the use of automatic rain gauges, by J. E. Codman. Observations were made continuously for three years with the object of showing what difference the size of the gauges would make in the amount of rainfall collected. The largest gauge had a diameter of over 22 inches, and the smallest 2 inches. The results show that the size of the gauge made no practical difference. He also gives the results of rainfall collected in gauges erected at

various heights on a mast. The result showed that a gauge at an elevation of 50 feet or less above the surface of the ground will collect the same amount as one on the ground, provided both are situated in a position not affected by counter currents of air. This result agrees with that found by Prof. Hellmann in his experiments at Berlin.—Sunshine recorders, by Prof. C. F. Marvin. Thus far two methods only have been in general use, (1) the focussing of the rays of the sun by means of a glass sphere and obtaining a burn on the surface of a card, and (2) the photographic method, producing a trace on sensitized paper. The first method records only bright sunshine, while the latter method is more sensitive and records fainter sunshine. Prof. Marvin has improved a method first developed by D. T. Maring of the Weather Bureau, consisting in principle of a Leslie differential air thermometer, mercury being used to separate the air in the two bulbs. When properly adjusted and exposed to sunshine the lower blackened bulb becomes heated and causes the column to rise above a platinum point and close an electric circuit. The instrument, of which a drawing is given, is said to respond promptly to sunshine and shadow. The other articles are.—Late investigation of thunderstorms in Wisconsin, by W. L. Moore.—Observations on the aurora of July 16, by T. W. Harris, and Temperature sequences, by Prof. H. A. Hazen.

THE articles in the *Journal of Botany* for November and December are mostly of interest to students of British botany. Mr. F. J. Hanbury adds two more to his new species of *Ilteracium*, *H. britannicum* and *H. caniceps*, Mr. Bagnall describes a new species of bramble, *Rubus mercurius* from the Midland counties, and Mr. W. H. Pearson a new British liverwort, *Scapania aspera*. Mr. G. F. Scott Elliot contributes some useful hints on botanical collecting in the tropics.

## SOCIETIES AND ACADEMIES

### LONDON

Royal Society, December 8, 1892.—“On the Photographic Spectra of some of the Brighter Stars” By J. Norman Lockyer, F.R.S.

The present communication consists of a discussion of 443 photographs of the spectra of 171 stars, which have been obtained at Kensington and Westgate-on-Sea during the last two years.

The chief instrument employed in this work has been a 6 inch refracting telescope in conjunction with—at different times—objective prisms of 7½° and 45° respectively.

By this method the time of exposure is short, and good definition, with large dispersion, is easily secured. The spectra thus obtained will bear enlargement up to thirty times without much sacrifice of definition.

The 30-inch reflector and slit-spectroscope at Westgate-on-Sea have also been used in the inquiry.

My object has not been so much to obtain photographs of the spectra of a large number of stars as to study in detail the spectra of comparatively few.

In the classifications of stars adopted by others from a consideration of the visual observations, only the broader differences in the spectra have been taken into account. Prof. Pickering has more recently employed a provisional classification in connection with the Henry Draper Memorial photographs of stellar spectra, but this chiefly relates to photographs taken with small dispersion. With larger dispersion it becomes necessary to deal with the presence or absence of individual lines.

In the first instance, the various stars of which the spectra have been photographed at Kensington have been arranged in tables, without reference to any of the existing classifications, and taking into account the finer details. The basis on which the main tabular divisions of the spectra are founded is the amount of continuous absorption at the blue end. This distinction was not possible in the case of the eye observations.

The stars included in the first table are characterized by the absence of any remarkable continuous absorption at the blue end, and by the presence in their spectra of broad lines of hydrogen. These have been further classified in four sub-divisions, depending on the presence or absence of other lines.

In the stars of the second table there is a considerable amount of continuous absorption in the ultra-violet, and the spectra beyond K are very difficult to photograph as compared with the stars of the first table. In these stars the thickness of the hydro-

gen lines is about the same as in the solar spectrum. These also are arranged in two sub-divisions.

In all the stars included in the third table there is a very considerable amount of continuous absorption in the violet, extending to about G, and it is a matter of great difficulty to photograph these spectra, as most of the stars of this class are below the third magnitude. The hydrogen lines are very thin. One sub-division includes the spectra which show flutings shading away towards the less refrangible end of the spectrum. The other comprises stars without flutings in their spectra. The brightest star in this table,  $\alpha$  Orionis, is discussed in detail, the result tending to show that the temperature of the absorbing iron vapours is not much greater than that of the oxy hydrogen flame.

The relations of the various sub-divisions to which reference has been made are then traced.

One important fact comes out very clearly, namely, that whether we take the varying thicknesses of the hydrogen lines or of the lines of other substances as the basis for the arrangement of the spectra, it is not possible to place all the stars in one line of temperature. Thus, there are stars in which the hydrogen lines are of the same average thickness, while the remaining lines are almost entirely different. These spectra cannot, therefore, be placed in juxtaposition, and it is necessary to arrange the stars in two series.

The next part of the paper consists of a discussion of the photographic results in relation to the meteoritic hypothesis. In the Bakerian Lecture for 1888, I brought together the various observations of the spectra of stars, comets, and nebulae, and the discussion suggested the hypothesis that all celestial bodies are, or have been, swarms of meteorites, the difference between them being due to different stages of condensation. The new classification rendered necessary by this hypothesis differed from previous ones, inasmuch as the line of evolution followed, instead of locating the highest temperature at its commencement, as demanded by Laplace's hypothesis, placed it much later. Hence bodies of increasing temperature were demanded as well as bodies of decreasing temperature.

The question how far this condition is satisfied by the new facts revealed by the photographs is next discussed.

This involves the consideration of some points in connection with the hypothesis to which brief reference alone has been made in previous communications. The phenomena to be expected on the hypothesis, and the actual facts, are given side by side below —

#### *Nebulae.*

The bright lines seen in nebulae should have three origins —

(1) The lines of those substances which occupy the interspaces between the meteorites. Chief among these, from laboratory experiments, we should expect hydrogen and gaseous compounds of carbon.

(2) The most numerous collisions between the meteorites will be partial ones—mere grazes—sufficient only to produce comparatively slight rises of temperature.

(3) There will, no doubt, be a small number of end on collisions, producing very high temperatures, and there should be evidence of some high-temperature lines.

(1) Lines at wave lengths approximately very closely to the lines of hydrogen, and to some of the carbon flutings, appear in the spectra of nebulae.

(2) There is a fluting most probably due to magnesium at  $\lambda$  500, and the longest flame lines of iron, calcium, and magnesium are seen.

(3) The chromospheric line  $D_1$  and another line at  $\lambda$  4471 (which is always associated with  $D_1$  in the chromosphere) have been recorded in the spectrum of the Orion Nebula.

#### *Bright-Line Stars*

The lines seen in the spectra of bright-line stars should, in the main, resemble those which appear in nebulae. They will differ, however, for two reasons given in the paper.

Prof Pickering has shown that the Draper Memorial photographs prove that bright-line stars are intimately connected with the planetary nebulae, the lines in the spectra being almost identical.

#### *Stars of Increasing Temperature*

*Stage 1* —Immediately following the stage of condensation giving bright line stars, the bright lines from the interspaces will be masked by corresponding dark ones, due to absorption of the same vapours surrounding the incandescent meteorites, and these lines will therefore vanish from the spectrum.

Owing to the interspaces being restricted, absorption phenomena will be in excess, and low-temperature metallic fluting absorption will first appear. The radiation spectrum of the interspaces will now consist chiefly of carbon.

Under these conditions the amount of continuous absorption at the blue end will be at a maximum.

*Stage 2* —With further condensation, the radiation spectrum of the interspaces will gradually disappear, and dark lines replace the fluting absorption owing to increase of temperature, though this line absorption need not necessarily resemble that in the solar spectrum.

*Stage 3* —(1) The line absorption and the continuous spectrum at the blue end will diminish as the condensations are reduced in number, as only those vapours high up in the atmospheres surrounding the condensations will be competent to show absorption phenomena in consequence of the bright continuous spectrum of the still disturbed lower levels of those atmospheres.

(2) Lines of iron and other substances will disappear at this stage, because the bright lines from the interspaces will counteract the lines in the same positions due to absorption of surrounding vapours.

(3) The chances of violent collisions being now enormously increased, we should expect the absorption of very high temperature vapours. The solar chromospheric lines may be taken as examples of lines produced at such temperatures.

The spectra of stars given in the third table answer these requirements. They show no bright lines under normal conditions.

The dark flutings in the visual spectrum agree very closely in position with the flutings seen in the flame spectra of manganese, lead, and iron. The evidence afforded by the photographs proves the actual presence of carbon radiation.

The photographs show a considerable amount of continuous absorption in the ultra-violet and violet.

The spectra consist of numerous dark metallic lines, but they do not exactly resemble the solar spectrum.  $\alpha$  Tauri and  $\gamma$  Cygni are types of stars at this stage.

(1) These conditions are satisfied by such stars as  $\alpha$  Cygni, Rigel, Bellatrix,  $\delta$  Orionis, and  $\alpha$  Virginis. In these there is no continuous absorption at the blue end, the spectra consisting of simple line absorption.

(2) In the spectrum of  $\alpha$  Cygni, which represents the earliest example of this stage, there are a few of the longest lines of iron, but in other stars of this class the iron lines disappear.

(3) The new lines which appear include the chromospheric line at  $\lambda$  4471, and possibly a few others.

#### *The Hottest Stars*

The order of the absorbing layers should follow the original order of the extension of the vapours round the meteorites in the first condition of the swarm, and the lines seen bright in nebulae, whatever their origins may be, should therefore appear almost alone as dark lines.

In stars like  $\alpha$  Andromedae we have absorption lines agreeing in position with some of the bright lines which appear in nebulae.

### \* Stars of Decreasing Temperature

*Stage 1*—Owing to the diminishing depth of the absorbing atmosphere, the hydrogen lines will, on the whole, get thinner, and new lines will appear. These new lines will not necessarily be identical with those observed in the spectra of stars of increasing temperature. In the latter there will be the perpetual explosions of the meteorites affecting the atmosphere, whereas in a cooling mass of vapour we get the absorption of the highest layers of vapours. The first lines to appear, however, will be the longest low temperature lines of the various chemical elements.

*Stage 2*—The hydrogen lines will continue to thin out, and the spectra will show many more of the high-temperature lines of different elements. These will differ from the lines seen in stars of increasing temperature owing to the different percentage composition of the absorbing layers, so far as the known lines are concerned.

*Stage 3*—With the further thinning out of the hydrogen lines and reduction of temperature of the atmosphere, the absorption flutings of the compounds of carbon should come in.

Taking Sirius as a type of stars in the first stage of decreasing temperature, it is found that its spectrum shows many of the longest lines of iron.

The conditions at this stage of cooling are satisfied by such stars as  $\beta$  Arietis and  $\alpha$  Persei. In the spectrum of these stars nearly all the solar lines are found, in addition to fairly broad lines of hydrogen.

There is undoubted evidence of the presence of carbon absorption in the solar spectrum and the spectrum of Arcturus, the only star which has yet been investigated with special reference to this point.

The photographs, then, give us the same results as the one formerly obtained from the eye observations.

Comparison is then made between the groups in the classification first suggested by the eye observations, and the various sub-divisions in which the photographs have been arranged.

Geological Society, December 7.—W. H. Hudleston, F.R.S., President, in the chair.—The following communications were read.—Note on the Nufenen stock (Leontine Alps), by Prof. T. G. Bonney, F.R.S. In 1889 the author was obliged to leave some work incomplete in this rather out of the way portion of the Leontine Alps. In the summer of 1891 he returned thither in company with Mr. J. Eccles, F.G.S., and the present note is supplementary to the former paper. The Nufenen stock was traversed from north to south, and a return section made roughly along the eastern bank of the Gries Glacier. Gneiss abounds on the north side of the Nufenen Pass, followed by rauchwacké and some Jurassic rock. On the flank of the mountain are small outcrops of rauchwacké and of the so-called "Duthene schists" (both badly exposed), followed by much Dark-mica schist, often containing black garnets. Higher up is a considerable mass of Jurassic rock with the "knois" and "irlams" which have been mistaken for garnets and staurolites, but Dark-mica schists set in again before the summit is reached. They continue down the southern flank of the peak; but rather north of the lowest part of the water shed, between Switzerland and Italy, the "Duthene schist" is again found, followed by a fair-sized mass of rauchwacké. The return section gave a similar association in reverse order, and both confirmed the conclusions expressed by the author in 1890 as to the absence of garnets and staurolites from Jurassic rocks (with belemnites, &c.), and the great break between these and the underlying rauchwacké (where it occurs) and the crystalline schists, in which garnets often abound, of the Leontine Alps. The crystalline schists and the Mesozoic rocks are thrown into a series of very sharp folds, which, locally, prevents at first sight the appearance of interstratification.—On some schistose

"greenstones" and allied hornblende schists from the Pennine Alps, as illustrative of the effects of pressure metamorphism, by Prof. T. G. Bonney. The author describes the results of study in the field, and with the microscope, of (a) some thin dykes in the calc schist group, much modified by pressure, (b) some larger masses of green schist which appear to be closely associated with the dykes, (c) some other pressure modified greenstone dykes of greater thickness than the first. The specimens were obtained, for the most part, either near Saas Fee or in the Binnenthal. These results, in his opinion, justified the following conclusions—(1) That basic intrusive rocks, presumably once dolerites or basalts, can be converted into foliated, possibly even slightly banded, schists, in which no recognizable trace of the original structure remains. (2) That in an early (possibly the first) stage of the process, the primary constituents of the rock-mass are crushed or sheared, and thus their fragments frequently assume a somewhat "streaky" order, that is to say, the rock passes more or less into the "mylonitic" condition. (3) That next (probably owing to the action of water under great pressure) certain of the constituents are decomposed or dissolved. (4) That, in consequence of this, when the pressure is sufficiently diminished, a new group of minerals is formed (though in some cases original fragments may serve as nuclei). (5) That of the more important constituents hornblende is the first to form, closely followed, if not accompanied, by epidote, next comes biotite (the growth of which often suggests that by this time the pressure is ceasing to be definite in direction); and, lastly, a water clear mineral, probably a feldspar, perhaps sometimes quartz. (6) That in all these cases the hornblende occurs either in very elongated prisms or in actual needles. The author brings forward a number of other instances to show that this form of hornblende may be regarded as indicative of dynamometamorphism, so that rocks where that mineral is more granular in shape (cases where actinolite or tremolite appears as a mere fringe being excepted) have not been subjected to this process.—On a secondary development of biotite and of hornblende in crystalline schists from the Binnenthal, by Prof. T. G. Bonney. Both the rocks described in this communication come from the Binnenthal, and were obtained by Mr. J. Eccles, F.G.S., in the summer of 1891. They belong to the Dark-mica schists described by the author in former papers, and have been greatly affected by pressure. In each a mineral above the usual size has been subsequently developed. In the rock from near Binn this mineral is a biotite the dimensions of one crystal, irregular in outline, and having its basal cleavage roughly perpendicular to the lines indicative of pressure, are about  $175 \times 0.3$ . The other mineral, from the peak of the Hohen Sandhorn, is a rather irregularly formed hornblende, the crystals (which lie in various directions) being sometimes more than half an inch long. The exterior often is closely associated with little flakes of biotite. The author discusses the bearing of this fact, and the circumstances which may have favoured the formation of minerals, so far as his experience goes, of an exceptional size. Some remarks also are made on relation of these structures developed in the Alpine schists to the various movements by which those rocks have been affected, and on the general question of pressure as an agent of metamorphism. The reading of these papers was followed by a discussion, in which the President, Mr. Eccles, the Rev. E. Hull, Mr. Rutley, Mr. Teall, and the author, took part.—Geological notes on the Bridgewater District in Eastern Ontario, by J. H. Collins.

### PARIS

Academy of Sciences, January 2.—M. d'Abbadie in the chair.—M. Lœwy was elected Vice-President for 1893. MM. Fizeau and Fremy were elected into the central committee of administration. The President gave a list of the members, associates, and correspondents deceased and elected during 1892. The new members were MM. Appell, Perrier, Guyon, and Brouardel. Foreign associates, MM. von Helmholtz, and van Beneden. Correspondents, MM. Sophus Lie, Considère, Amisler, Auwers, Rayet, Perrotin, de Tillo, and Manen.—Observations of Brooks's comet (November 19, 1892) made with the *equatorial coude* of the Lyon Observatory, by M. G. Le Cadet.—On a new method of approximation, by M. E. Jablonik.—On the movements of systems whose trajectories admit of an infinitesimal transformation, by M. Paul Painlevé.—On the general form of vibratory motion in an isotropic medium, by M. E. Mercadier.—On thermo-electric phenomena between two

electrolytes, by M. Henri Bagard. The thermo-electric force between two portions of the same electrolyte in different stages of dilution was determined by experiments performed at the physical laboratory of the Faculty of Sciences at Nancy. The diaphragm employed consisted of goldbeater's skin, which has the advantage of closely adhering to the glass. The results are given in the case of zinc sulphate. With a 5 per cent and a 45 per cent solution the difference of potential ranged from 78 at 17° 9' to 155 at 73° 5', the unit being 1/10000th of the E.M.F. of a Daniell cell. The law of intermediate bodies was strictly fulfilled, as shown by opposing a couple of 5 and 25 per cent in series with another of 25 and 45 per cent to a third of 5 and 45 per cent., when no deflection of the electrometer was observed between 0° and 73° 3'. On the age of the most ancient eruptions of Etna, by M. Wallerant. The first eruptions of Etna have been variously estimated to have occurred in the later quaternary or in the upper pliocene periods. These conclusions were based on the study of the prismatic basalt laid bare by the sea round the foot of the cone. The pliocene deposits found in conjunction with part of the basalt appear from palæontological evidence to be contemporaneous with the sub-Apennine blue marls, which belong to the lower pliocene. In the Cyclopean Isles the basalt is covered with a layer of clay, which is also found interperated by the basalt. The identity of age of the two formations is evidenced by lenticular patches of sand interstratified in the clay, whose particles consist of fragments of pyroxene, peridot, and trichitic feldspar, proving that when the sub-Apennine marls were being deposited Etna was the scene of eruptions accompanied by the emission of ashes.

## HEREDITY.

*Das Keimplasma Eine Theorie der Vererbung.* By August Weismann, Professor in Freiburg i B (Jena. Gustav Fischer, 1892)

IN the substantial volume whose title stands at the head of this article Prof Weismann has gathered together the results of the essays and researches which he has given to the world during the last eleven years, and he now presents us with a theory of heredity, for which his previous writings have been but preparatory.

Those who have followed the German philosopher since the appearance of "*Die Dauer des Lebens*" in 1882 have traversed a wide territory. They have seen many theories and hypotheses come into view and attain a certain degree of definiteness. Some of these are now lost to sight, others have changed their outline and altered the relative proportion of their parts, but, whatever was the standpoint, the central feature of Prof Weismann's theory of heredity—the continuity of the germ-plasma—remained unchanged.

The work before us consists of an introduction, partly historical, and of four books, in which the theory and its application to various biological problems are set forth in the fullest possible manner, and in language for the most part free of technical phrases, so that a non-scientific reader can easily follow the argument. At the close of the volume are a summary of the four books and an index. The latter is a novelty in a German book of this kind, for which we cannot be too grateful to its compiler, Fraulein Diestel.

The title of the work strikes the key-note of Prof Weismann's theory. Heredity, according to his view, is brought about by the transference from one generation to another of a substance with a definite and very complex constitution, the germ-plasma. This substance is the material basis of heredity, and it is supposed that a part of it in each reproductive cell is not used up in the construction of the offspring, but is transmitted unchanged to form part of the reproductive cells of the following generation. As the author points out, his theory might be termed "*Blastogenesis*," or the origin from the germ-plasma, as opposed to Darwin's "*Pangensis*," or the origin from all parts.

This germ-plasma is necessarily a most complicated substance, it cannot arise anew, but can grow and increase. Its ultimate constituents, according to the latest view of the Freiburg professor, are certain units termed biophores, which possess the properties of assimilation, growth, and multiplication by means of fission. So long as the organic world consisted of biophores living either singly or united in colonies, heredity and multiplication with subsequent growth were one, since each division resulted in two similar halves, which by growth gave rise to organisms exactly like the parent.

But, when the principle of the division of labour made itself felt, the biophores became differentiated, and simple division no longer sufficed to give rise to two similar organisms, each exactly like their parent. A special

mechanism was needed to bring about heredity, and according to our author this was found in the nucleus. This differentiated part of the cell was originally a collection of reserve biophores. After the division of the nucleus the biophores in each half multiplied, and so replaced those which had separated from them, and thus rendered possible the completion of the new organism. The structure of the nucleus became still more complicated when amphimixis, the mingling of the hereditary substance of two individuals, made its appearance. Amongst multicellular organisms, with their endless variety of cells, the same mechanism exists, but in a still more complicated form. Sexual reproduction has arisen, that is, the "*Anlagen*" for the whole organism are collected into a single reproductive cell, two such cells come together, and the resulting fertilized egg cell contains the hereditary substance of two individuals.

According to Prof Weismann's present view, this hereditary substance or germ-plasma consists ultimately of biophores. These units are built up in a definite order and arrangement into units of the second degree, which are termed "*cell determinants*," or simply "*determinants*." Every cell of a multicellular organism is dominated in its histological character, and in the rhythm and nature of its division by one of the determinants. Each cell has not, however, a corresponding determinant in the germ-plasma, but cells of the same sort, as, for instance, blood corpuscles, may be represented in the hereditary substance by the same determinant. In the germ-plasma of any species there must be as many determinants as there are variable cells or cell groups in the organism. The determinants are arranged in a definite order in units of the third degree termed "*ids*."

These ids, which will be familiar to readers of Prof Weismann's latest essay, that on Amphimixis, are again built up into idants, and these last probably correspond with the chromatosomes, or nuclear rods of the nucleus. Thus the germ-plasma consists of idants, the idants are composed of ids, the ids are built up in a definite manner of determinants, and the determinants are formed of the final units, the biophores.

It is assumed that the biophores can pass out of the nucleus and divide and multiply in the surrounding cell protoplasm. Amphimixis brings about the mingling of a certain number of biophores from one parent with a similar number from the other, and the organism whose body is dominated by this mixed assemblage of biophores partakes of the nature of both parents.

In the reproductive cells of the higher plants and animals the nucleus must contain not only those determinants which dominate the structure, rate of division, &c, &c, of the cell itself, but also those which will dominate the various cells and systems of cells which will eventually arise from the reproductive cell, and furthermore these must be definitely arranged in a given order, so that they may not be all called into activity at once, but may become functional successively, in accord with the origin of the cells they control.

It is not possible within the limits of a short article to describe the many ingenious applications of his theory, by means of which Prof. Weismann attempts to explain such phenomena as the Regeneration of lost parts, Reversion, Budding, Alternation of Generations, &c.: all

these are brought into line, and are shown to be capable of an explanation in the theory of germ plasma. Dimorphism and seasonal dimorphism are explained by the assumed existence of double determinants, one corresponding with each form, and remaining inactive during the life-time of the organism controlled by the other.

Such changes as affect the cell body cannot be transmitted according to this view, since alterations in the cell have no effect upon the biophore which in the next generation will dominate the corresponding cell of the offspring. But, since variation must be ultimately dependent on external circumstances, influences such as climate, change of food, &c., are considered to have in the course of time some effect upon the determinants, and a corresponding change in the organism results. In this lies one of the chief differences between the germ-plasma theory of Prof. Weismann and the Pangenesis of Darwin. They both give a possible explanation of heredity, but in the latter case the gemmules, coming from every cell of the body, afford an explanation of the transmission of acquired somatic changes, in the former case the biophores, arising only from other biophores, would be uninfluenced by any such change.

A E S

### THE BASIS OF ALGEBRA.

*The Algebra of Co-planar Vectors and Trigonometry*. By R. Baldwin Hayward, M.A., F.R.S., Senior Mathematical Master in Harrow School, formerly Fellow of St John's College, Cambridge (London: Macmillan & Co., 1892).

THIS work is constructed on the methods of the school of mathematicians who derived their inspiration from the teaching of De Morgan, a school which is represented by many of the most influential of our recent writers on mathematical subjects. It is intended to occupy the place of the "Trigonometry and Double Algebra," published in 1849 and now a long time out of print, at the same time incorporating such improvements in elementary treatment as have been evolved out of half a century's discussion of the foundations of Algebra. Those who are acquainted with Mr Hayward's other writings, such as his "Elements of Solid Geometry," will expect a fresh and interesting treatment of his subject; and they will not be disappointed. On turning over the pages we constantly come across elegant touches and happy turns of expression, and historical appreciations—the stuff which constitutes the basis of literary excellence in mathematical writings.

The treatise is primarily concerned with the logical exposition and illustration of the principles on which Algebraic Analysis, including Analytical Trigonometry, is founded. The utility of this subject in its practical applications renders it a necessary part of even an elementary course of reading, while a very refined treatment of it may lead so far into the notions of the Theory of Functions and algebraic continuity in general, as to somewhat overlay the really simple matters with which it is concerned. In this country the tendency in elementary books has, until recently, been rather to take the fundamental formulæ on credit, and to make the subject

consist of the development of their analytical and practical consequences. The philosophical principles which bind them into an organic whole have retained so much the aspect of *a posteriori* developments, that there is some temptation to proceed in the view that Mathematical Analysis is an inductive science like Natural Philosophy, that it is one part of the science to invent and verify the formulæ, while the logical calculus which gives them precision and limitation is quite another department. The great majority of readers of the elements of Algebra have no time for an exhaustive discussion of the nature of continuous quantity and all the types of singularity to which it is liable, while on the other hand complete neglect of the logical basis of Analysis deprives it both of a main source of its interest, and of a large part of its value as an intellectual training. Hence arises the importance, even in presence of the complete theory with which a specialist must be acquainted, of the simplification and improvement of methods of exact treatment within the domain of elementary ideas.

The author's method starts off from an *a priori* discussion of the Algebra of Co-planar Vectors, which leads him to the two modes of specification of a vector, as a power of the fundamental vector, and as a sum of components. The identification of these two expressions leads to the analytical definitions of the *sine* and *cosine*, and by way of certain theorems in algebraic limits [whose explicit enunciation is by the way not essential] to the orderly development of the subject. The theorems concerning series which involve the complex variable are strikingly illustrated by corresponding vector chains, and geometrical interpretations are throughout very copious. The treatment is here so full and many-sided, that it would form an interesting occupation for the reader to take up the other aspect of the matter, and try to pick out the simplest and briefest analytical foundation on which the formulæ required for practical applications may be built.

The remarkable formula of p. 115,  $(4.810475 \dots)^{-1}$ , if removed from the context in which it is set, might be propounded as a puzzle in interpretation. The author introduces us straight off to an expression with a complex index, and proceeds to ascertain whether any meaning can be assigned to it, which will allow the inclusion of such expressions in the algebraic calculus. The geometrical method gives him very neatly and definitely an expression for the values of  $A^B$ , where  $A$  and  $B$  are both complex, by means of the vector ribs of a fan of equiangular spiral form. But when the conception of logometers (analytical logarithms) to a vector base comes up for interpretation, the answer proves to be some one of an infinite-infinite series of vectors related to one another in a manner so complicated as to elude definite grasp; and we have arrived at a case in which the inclusion of the function in our calculus would, in the absence of special machinery of representation like a Riemann's surface, be best avoided.

The origin of all difficulty in the treatment of complex algebra lies in fact in the multiplicity of values of the functions with which it deals. If each function can be defined as spread out in a multiple sheet so as to be single-valued at each point on each leaf of the sheet, a great part of the trouble disappears. We can then if we

please make explicit use of the Principle of the Permanence of Equivalent Forms, which, after having been expounded at length and defended by Peacock (appendix to "Algebra"), has been summarily rejected as misleading and unmeaning by many recent authors. To the formal reintroduction of this principle Mr Hayward's language exhibits a tendency to return. Outside the domain of elementary Algebra, its strict employment in the prolongation of an analytical function into a new region is indeed of common occurrence in Analysis; while its tentative application in unrestricted form, as an instrument of suggestion and discovery in the Theory of Operations, is fundamental. To the effort to widen the limits of interpretation in connexion with it, has been due most of the advances in Analysis.

It is a fundamental question in mathematical logic how far, after having carried the stream of our analysis through regions of uninterpreted symbols, and having at length arrived at a stage in which these symbols have disappeared, we are entitled to claim this procedure to be demonstrative. It is of course of the very essence of Algebra that the intermediate steps of its analysis remain uninterpreted, though in the Algebra of real quantities we have a tacit assurance that an interpretation can be supplied if necessary. Why then was there an objection to a similar procedure in the Algebra of complex quantities, and what is the source of the timidity and doubt which characterized the use of complex analysis before its geometrical interpretation was developed? Simply that complex quantities turned out to be multiple-valued, and that the selection of the proper value under given circumstances had to be settled by tracing the continuity of the quantities in a way that was to the mind practically impossible until a visual geometric representation was discovered. The Argand diagram is not essential to the logic of the matter, it rather makes Analysis possible by bringing its scope within our grasp. It simply forms a more extensive and systematic example of the method which has been in use since the time of Descartes for studying functions and approximating to their roots, by aid of their graphical representation.

The Principle of Permanence of Equivalent Forms thus lies at the very root of Algebra, but it is rendered ineffective by indeterminateness of interpretation. Its strict use, when most needed, is subject also to another hitch. It requires that the forms be expressed in exact terms, an infinite series must be expressed in the sum of  $n$  terms together with a residue  $R$ . These residues must be retained throughout the analysis until we arrive at a point where interpretation comes in, and it must then be settled how far they can be neglected in the circumstances of the actual interpretation. In the language of Mr Hayward, it cannot be asserted about series that are not absolutely convergent, that the fundamental laws of Algebra hold without limitation.

It is perhaps a question how far the idea, thus restricted and safeguarded, is worth being expressly retained as a working principle of ordinary Algebra. In subjects like the Calculus of Operations and Finite Differences, which are still in an unsystematized stage, it cannot be dispensed with; and the extent to which its use is boldly pushed, by De Morgan and Boole, even to the discussion in an operational manner of divergent series without their

residues, contrasts with the more exact processes of recent Analysis. How far this boldness arises from the profound logical studies of these writers, and their appreciation of the imperfect character of inference at the best, may be a subject open to discussion.

In connexion with the doctrine of convergence of series, the author gives a very clear account, from Sir G. Stokes, of how it is that, on approaching certain critical points, the convergence may gradually fall off and finally disappear. The illustrations employed are algebraic series of an exceptional character, and the whole circumstances may possibly suggest to the uninitiated that it is a phenomenon of exceptional rarity. The most natural context is, of course, in connexion with the wonderful and far-reaching theory initiated by Fourier, by means of which functions arbitrarily discontinuous are expressed by seemingly continuous series. In that connexion, the necessity of explanation is so obvious that it is interesting to examine the previous attempts at elucidation. Thus De Morgan, in 1839, is able to conclude ("Diff and Int Calc.," pp 233, 239) that such discontinuity cannot occur in series proceeding by powers of a real variable, that in other cases it occurs only through the series becoming divergent at the point of discontinuity. It is, however, an important question how far it would be allowable to avoid burdening an elementary exposition by complete precautions against the existence of anomalies like this, which would hardly have originally occurred to any one in that early stage.

The book ends with a wider survey, including a clear and interesting account of Cauchy's theory of the radical points of a rational function. The graphs of the cubic  $x^3 + ax$ , which are given as an illustration, would also form excellent and rapid examples of the Rankine-Maxwell method of graphical addition, applied to the separate graphs of  $x^3$  and  $ax$ .

#### FOSSIL PLANTS AS TESTS OF CLIMATE

*Fossil Plants as Tests of Climate, being the Sedgwick Prize Essay for the Year 1892* By A C Seward, M A, F G S, Lecturer in Botany in the University of Cambridge (London: C. J. Clay and Sons, Cambridge University Press, 1892.)

THIS admirable essay is really a digest of the opinions of the principal writers on fossil plants, so far as they throw light on geological climates, and a critical résumé of the subject up to date. It should be read by all who prefer to deduce the relative temperatures of various latitudes in the past from such solid data as assemblages of ferns, cycads, and conifers, the ancestors of living genera and species, rather than from utterly extinct belemnites, ammonites, and saurians, of whose habits little can ever be known, and which might have drifted far out of their temperature zones by warm and cold sea-currents.

Perhaps if any criticism can be made, it is that too little has been said by the author as to what is known of the Mesozoic floras, which, if scanty, are extremely interesting. In fact only the widely separated Palaeozoic and Cenozoic floras are fully dealt with. Owing to the magnitude, difficulty, and freshness

of the problems presented by the former, they have received the larger share of attention and have ever attracted some of the most acute and philosophic of scientific workers. But while the researches of such investigators as Williamson and Renault into the actual structures and affinities of the carboniferous plants have been rewarded with the most brilliant successes, attempts to speculate and theorize have only been productive of barren controversy. All inferences as to the temperatures in which they flourished have merely been inductions from unknown data: their affinities with existing plants are so remote that they can tell us of little beyond moist climates and spongy, marshy soils, liable to inundation, with possibly an atmosphere more highly charged with carbonic acid than at present. But that neither the flora nor identical conditions were uniformly present over the whole land during the deposition of the carboniferous, becomes every year more apparent, and perhaps few would now maintain that fossil floras met with in widely-different latitudes must necessarily be contemporary because similar, or reject as impossible the correlation of the *Glossopteris* floras of the southern hemisphere simply because they are so dissimilar.

Tertiary floras, however, have to be approached from almost totally different standpoints, for here minute investigations into vegetable structure can only exceptionally lead to important results. On the other hand it may be possible to predicate the climate that any group among them would have required, with almost perfect accuracy. Allowing that even most closely-allied species may have had different habits, enough remain that are practically identical with living species. These not only prove to us that in every land in our hemisphere the temperatures remained warmer throughout the Tertiary period than at present, but also that the temperatures were far more equable during Eocene time. Thus it is impossible to hesitate as to the evidence of the flora in the lower stages of our Eocene, which exhibits an abundance of planes, poplars, and alders and an absence of all approach to sub-tropical essences, nor as to that of the London Clay, with its tropical nipas, sabals, and a host of others almost indistinguishable from species existing at the present day. There is scarcely need of the corroborative evidence of the Mollusca as to cooler seas in the Thanets, nor of tropical conditions in the large turtles, crocodiles, snakes, and nautili of Sheppey. In fact, the temperature of the spots occupied by Reading, Bournemouth, or Mull at a particular stage of the Eocene could be predicated from the fossil floras almost as accurately as from living plants. If the same cannot be said of the Arctic regions it is simply that the specimens brought home are, perhaps from the exigences of travel and inexperience of the collectors, for the most part so imperfectly preserved and fragmentary, that few of the determinations can carry the smallest weight. It may suit quidnuncs to accept indeterminable fragments as evidence of the growth of palms and cycads in the Greenland Eocene—it is time the Miocene age of these beds was relegated to the limbo of Coal-measure palms and yuccas—and to become excited over the presence of a sub-tropical flora within the Arctic circle; but as a fact it is doubtful whether anything has been discovered there which might not have grown in our own temperature, if

slightly modified, a state of things which it is conceivable the damming back of the Arctic seas by the land connection which then existed between Europe and America, aided by an active Gulf Stream, might have brought about. When we come to the Miocene, worked out as that of Switzerland was by Heer, or still more the Quaternary, with such data as those laboriously amassed by Clement Reid, the inferences as to climate are still more irresistible.

As to evidence of the age of rocks, plants are less trustworthy, because they have neither been so perfectly studied nor are their zones as yet at all properly defined. All we can say is that certain assemblages are found in association at the beginning of the Tertiary, and that changing temperatures have since compelled them not to disperse, but to migrate far and wide. Fewer probably of the species are extinct than is generally supposed, and the primitive associations have held together perhaps to the present day, with many gaps from extinction and desertion and a large infusion of recruits through the ordinary causes of evolution, stimulated by the increase in browsing mammalia. Whether, on the other hand, the marine deposit zones are really entitled to the weight attached to them as evidences of age, except locally, is not so clear. They are usually the littoral deposits of a limited area, where some changes of level or current have apparently suddenly driven out the fauna and introduced new colonies more adapted to the changed conditions. If we could follow the subsequent wanderings of these assemblages under the sea our faith in their sudden extinction and consequently in their chronological value might be greatly modified. At all events, many of the less conspicuous groups of mollusca, when critically examined, prove to have surprisingly near relatives in distant seas at much later periods, and even at the present day.

J. STARKIE GARDNER

#### OUR BOOK SHELF

*Pioneers of Science*. By Oliver Lodge, F.R.S. (London and New York: Macmillan and Co., 1893.)

THIS book consists of eighteen lectures on the history and progress of astronomy, which were delivered by Dr. Lodge in 1887. "The lectures having been found interesting," he thought it "natural to write them out in full and publish," and, although this can scarcely be considered a sufficient excuse, the intrinsic merits of the work are abundant justification for its existence. In Part I, "From Dusk to Daylight," the progress of astronomy from Copernicus to Newton is traced in a series of vivid pictures of Copernicus, Tycho Brahe, Kepler, Galileo, Descartes, and Newton; while Part II, "A Couple of Centuries' Progress," brings the history of gravitational astronomy from Newton down to the present time. In these latter lectures Roemer and Bradley are associated with the velocity of light and aberration, Lagrange and Laplace with the solar system and the nebular hypothesis; Herschel with the motion of "fixed" stars; Bessel with the distances of stars, Adams and Leverrier with the discovery of Neptune, and Lord Kelvin and George H. Darwin with tides. Dr. Lodge has been able, by judiciously combining clear statements of scientific facts and laws with interesting personal details, to give his lectures all the charm of a romance. The book is an admirable introduction to the study of astronomy, and no better gift for a beginner could well be chosen, while to those to whom many of

Its details are already familiar, the picturesque clearness with which they are presented will make their knowledge more real and more complete. The standard of excellence maintained in the lectures makes distinction difficult and invidious, or we would distinguish the lectures on Newton and those on tides as models of what such popular scientific expositions should be. The book is copiously, and, on the whole, well illustrated, but some of the illustrations—notably those of clusters and nebulae—are very familiar and somewhat out of date. A curious mistake occurs on page 291, where a well-known drawing of a comet appears as an "old drawing of the Andromeda nebula." The illustration on page 326, showing the paths of Uranus and Neptune and their relative positions from 1781 to 1840, and professing "to illustrate the direction of their mutual perturbing forces," is partly misleading, but in introducing this Dr. Lodge has erred in good company, for the diagram, originally due to Dr. Houghton, appears in many of our recent astronomical text-books. A 1

*Electric Lighting and Power Distribution* Part I By W. Perren Maycock, M.I.E.E. (London: Whittaker and Co., 1892)

THIS cheap and useful little text-book has been written for the author's junior students, as he is of opinion that no trustworthy elementary work on the subject is to be obtained. The scope of the work has been limited to the syllabus of the ordinary grade examination of the City and Guilds of London Institute. We find, however, much information on subjects not usually found in other manuals. The book is freely illustrated, and the descriptions are clear.

It is very important for the junior student to understand clearly what is meant by a line of force, and to grasp the fact that lines of force are only assumed to exist, because, by such an assumption it is possible to explain many, otherwise inexplicable, phenomena. On page 47 we find the following statement—"The power which any magnet possesses, of picking up pieces of iron, and of acting upon another magnet, depends upon the existence of lines of magnetic force." This quotation is vague, a junior student might easily imagine that the lines of force really existed, whereas they are purely assumptions, to elucidate the phenomena of magnetic attraction. The illustrations of simple bar magnets, solenoids, and electro-magnets, in which the lines of force are delineated, should have the assumed directions of the lines of force clearly shown by arrow-heads. This might be done with advantage in Figs. 17 to 20.

Chapter IV deals with induction of currents, electromagnetic induction, Faraday's Law, and concludes with a clear description of magneto-motive force, magnetic resistance, magnetizing force, induction and permeability. These latter are very difficult for a junior student to understand thoroughly, and the author should have devoted more space to the discussion of these important points in dynamo construction. One particularly good feature in this text-book is the large number of questions arranged at the end of each chapter. These are well suited to test the knowledge of a student. Chapter V deals generally with electrical testing, measuring instruments used in installations, and meters for measuring the current, such as Teague's, Elibu Thomson's, and the Wright-Ferranti. Chapter VI concludes the book, describing the principle of the dynamo, different types of machines, and the construction of the various parts.

Taken as a whole this book attempts too much. The matter described has suffered considerably by condensation, a serious thing where junior students are concerned. Most of the illustrations are good, some are indistinct, and Fig. 98 is decidedly wrong, showing the brushes set for one direction of rotation, and the arrow indicating the reverse.

On the other hand the sequence of matter is good, and a student should learn much from the work. The author takes great pains to describe clearly the many units involved, particularly the applications of Ohm's law. The book would last much longer in the hands of the average student if the present paper binding were replaced by something stronger.

*The Naturalist on the River Amazons.* By Henry Walter Bates, F.R.S. With a memoir of the author by Edward Clodd. Reprint of the Unabridged Edition. With Map and Numerous Illustrations. (London: John Murray, 1892)

THIS work is so well known, and has long held so high a place among scientific books of travel, that it is unnecessary to do more than note the appearance of a new edition. It is clearly printed on good paper, and the illustrations are well reproduced. The introductory memoir by Mr. Clodd is a most welcome record of the main facts of Mr. Bates's career. The materials for this interesting sketch were enriched by letters placed at the author's disposal by Sir Joseph Hooker and Mr. Francis Darwin. An excellent portrait of Mr. Bates is included in the volume.

### LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### A Proposed Handbook of the British Marine Fauna

SUCH a handbook as Prof. Herdman suggests is so much wanted that many naturalists must from time to time have felt tempted to essay it. But the difficulties are very formidable. Prof. Herdman seems to contemplate the preparation of such a work mainly as a labour of compilation. But the groups where compilation would nearly suffice are just those where the handbook is least required. On the other hand, such a group as the Amphipoda, in spite of Canon Norman and Mr. Stebbing's many papers, is still in great need of revision; it was only the other day that Canon Norman opened our eyes to our rich fauna of Mysidae, before which time no search among published records would have told us anything worth the having; we are in just the same position as to our British Cumacea, until Canon Norman again reveals the treasures of his cabinet, our Pycnogonids are almost as little known. In every one of these groups, and in many others like them, the preparation of a hand-list would need the experience of a specialist, just as much as the Tunicata would require Prof. Herdman's own special knowledge. The area to be embraced is another difficulty. Prof. Herdman proposes to take the British area as defined by "Canon Norman's" B.A. Committee in 1887, on which he himself served. But the committee's report was repudiated by Canon Norman himself, who afterwards suggested a wider "British area," whose boundaries I fancied had since been recognized as more suitable by everybody. However the British area be defined, there will long remain a difficulty in the numerous forms not yet recorded from within it, but which are likely, or certain, to turn up when sought for. Such things as the parasitic and other Crustacea described of late years by Giaré and his pupils from Wumareux form a case in point. I am inclined to think that to make in the first instance a hand-list of the whole fauna of the North Atlantic basin would be not a bit more difficult, but in some respects easier, than to restrict the list to the British area alone. That it would be incomparably more useful is certain. It would make a book not more than three times (perhaps little more than twice) as big as Carus's "Fauna Mediterranea." And it would be a very important step towards that new *systema nature* of which the Germans are already beginning to talk, and which it is high time were begun.

But Prof. Herdman both asks discussion of his plan, and also invites criticism on his execution of it. Take his very first illustrative genus, which he tabulates as follows:—

ANTENNULARIA.—Stems simple or branched, pinnae verticillate; nematophores along the stems; gonothecae axillary, unilateral.

*A. antennina*, L., stems clustered, usually simple, hydrothecæ separated by 2 joints 6 to 9 in. high. Gen. distr. deep w.  
*A. ramosa*, Lamk., stems single, usually branched, hydrothecæ separated by 1 joint only 6 to 9 in. high. Gen. distr. deep w.

Now there are no nematophores along the stem, but only on the pinnae, *A. ramosa* may sometimes grow up unbranched, but I for one never saw it so, and *A. antennina* is always simple, save by the rarest individual abnormality, the dimensions are quite inaccurate, for we have *A. antennina* here of all sizes up to 24 inches high. The distribution given is too vague. In the report of the B. A. Committee, which Prof. Herdman goes by, deep water is defined as that below 100 fathoms, but these two are not deep water species, either in that or any other common use of the phrase. The authorities are very loosely given. *A. antennina*, L., should be (L.), and if the bracketed authority, i.e. the original user of the specific name, is to be the one quoted, then for *A. ramosa*, I think Lamk. should give place to (Lamk.). And why is the authority for the genus left out altogether?

Moreover, even if these definitions were verbally accurate so far as they go, they would only suffice to exclude one another, with no reference to other non-British species. They are rather definitions of groups of species or sub-genera, than of these two particular forms. It would not matter very much, perhaps, in this case, where other species are not likely to turn up upon our coasts, but such definitions, drawn with reference only to known British forms, would soon lead to hopeless confusion in the case of less known groups.

Dundee, January 11

#### On an Abnormality in the Veins of the Rabbit

AMONGST a number of rabbits dissected in my laboratory last term, one specimen exhibited a peculiarity in the venous system which is especially interesting in connection with Hochstetter's and Macalister's accounts of the development of the veins. Unfortunately the specimen had been too far dissected before the abnormality was noticed to follow out every detail.

The blood from the hinder extremities, urinogenital organs, and abdominal walls, passed into a large vessel having the position and relations of a postcaval posteriorly. Instead, however, of passing through the dorsal border of the liver to penetrate the diaphragm, it was seen at the anterior part of the abdomen to correspond to the azygos, receiving the superior intercostal veins, and opening into the right precaval. This vessel evidently, then, corresponded to the persistent right posterior cardinal. The portal system was apparently normal, and the hepatic veins opened into a postcaval, which extended through the diaphragm to the heart in the usual manner.

Thus the independently-formed section of the postcaval (*Leberabschnitt*) had taken on no connection with the part developed from the cardinals (*Urmerenabschnitt*), but had remained as a separate vein, bringing back the blood from the alimentary organs (and ? diaphragm) only.

I have not thought it necessary to do more than mention these facts, as the whole question has recently been fully discussed by Dr. A. Robinson ("Abnormalities of the Venous System and their relation to the Development of Veins," "Studies in Anatomy from the Anatomical Department of the Owens College," vol. 1 p. 197, Manchester, 1891). The above case, however, supports the view that the renal veins are direct tributaries of the right cardinal, and not of the postcaval; while the reverse conclusion is derived from Dr. Robinson's observations.

#### Difficulties of Pliocene Geology.

YOU were good enough to print a letter from me a week or so ago, in which I called attention to some of the difficulties in explaining the distribution of the so-called Pliocene beds. I should like to prosecute the subject a little farther.

The geographical distribution of the mastodon is assuredly one of the greatest paradoxes in natural science.

As is well known, it occurs both in North and South America, and on both sides of the Rocky Mountains and the Andes. It has not occurred, however, so far as I know, north of the great lakes in the east, nor of Oregon in the west, nor has it ever been reported from Alaska, where mammoth remains are so abundant. I do not know any evidence that it has been found anywhere in

Asia, north of the Himalayas, neither in China, nor Manchuria, nor Mongolia, nor Turkestan, nor in Siberia, nor has it occurred in European Russia, except close to the Black Sea, nor in Poland, nor in Scandinavia, nor in North Germany.

In the Old World its zone of distribution extended from India to the Pyrenees, including the Mediterranean borders, the valleys of the Danube, and the Middle Rhine, Eastern England, and perhaps Iceland, whence some teeth are said to have been sent to the royal collection at Copenhagen. This distribution of a very highly specialized beast is certainly most extraordinary. Granted that the mastodons of Western Europe and those of America are slightly different, the difference is so slight that, as Falconer says, Cuvier treated them as the same species, and they cannot have been very long isolated. Yet how are we to explain the facts, and do justice to the widespread view that the ocean areas are very old?

It seems to me as clear as anything can be that when the mastodon was distributed over Western Europe and America, there must have been a land communication between the two areas, and I cannot see how, with the facts before us, we can escape the conclusion that this connection must have been across either the Atlantic or the Pacific, not in high but in low latitudes, perhaps across both.

The mastodon is not the only animal which points the same lesson. The machairodus, a very highly specialized feline, has been found both in the Old and the New World, but did not inhabit the great palaearctic province of Europasia, east of the Rhine, nor America north of the great lakes. The American jaguar, a mere variety of the Old World leopard, is another animal with the same abnormal distribution, so are the American and the Old World tigers.

Now this connection between the Old and the New World cannot, so far as we can judge, have been in high latitudes, for the forms in question have not occurred in high latitudes. If the connection had been across the Northern Pacific, we should have had some remains of these animals in Japan, where more than one fossil elephant has occurred, or in the Sandwich Islands, which are, to all appearances, a very old land surface.

The connection must, therefore, if it was across the Pacific, have been across its more equatorial part. It seems similarly to follow from the absence of these animals in the high latitudes of America and Europe, save the doubtful case of Iceland, that in the case of the Atlantic also the land bridge must have been further south, and perhaps where the Atlantic islands still remain. One more inference. If there was a penannular or circular belt of land about the earth in the tropical or sub-tropical zone over which these beasts could travel, it would possibly account for the tertiary climate of high latitudes having been a warm one, as we know it was. A zone of land in the tropics would act as a furnace, whose heat would be widely distributed by the ocean currents in contact with it.

The views here urged, it will be said, are like those of the advocates of a Miocene Atlantis. They are in essence very different, and meant to explain a very different phenomenon, namely the aberrant and abnormal distribution of the mastodon and its companions. The mention of the Miocene Atlantis, however, suggests another and more critical difficulty in explaining the Pliocene beds, but this must be postponed to another letter.

#### Earthquake Shocks.

A SERIES of slight earthquake shocks have lately occurred in this district, viz. January 3, 2.15 p.m. at Severn Junction (E. J. L.); January 4, 11 a.m., Itton Court, Chepstow (a heavy plant stag in a greenhouse was seen to move four times by Mr. J. Curr and the Rev. N. S. Barthropp); January 5, between 2 and p.m., and again on the 6th (a little earlier), Llanthony Monastery (a rumbling noise on the Black Mountains near the monastery Mr. P. E. Hill); January 14, 6.55 p.m., a shock lasting more than a second, Bigwear House, Coleford, Mr. J. V. Newbery (Mr. Newbery has had experience of earthquakes, from a long residence in Japan).

E. J. LOWE.

Shrewton Hall, Chepstow.

#### The Weather of Summer.

I REGRET to find that, in making a quotation at the end of my letter last week (p. 246), I erred in supposing Mr. Symonds to be the writer. I beg to apologize for the slip. A. B. M.

ON THE ORIGIN OF THE ELECTRIC NERVES  
IN THE TORPEDO, GYMNOTUS, MORMY-  
RUS AND MALAPTERURUS

THE subject of this communication may seem remote and uninteresting, but it will not be difficult to show that questions of the highest importance for physiology, anatomy, and the Darwinian theory are closely related to those touching the structure of the electric organs of certain fishes and the laws of their functions.

The fact that the body of an animal should become a complete electrical apparatus acting at the will of its owner induces us to inquire how this extraordinary result has been attained, that is, to investigate the origin of the electric organs of fishes, and the manner in which the animal throws them into action. We shall see that in pursuing both lines of enquiry we open far-reaching views into regions as yet unknown.

According to the present state of our knowledge there can be no doubt that most of the electric organs hitherto discovered are of muscular origin. It is not my intention to dwell on this transformation of muscular tissue, but it may nevertheless prove interesting to cite an example of

The well-known electric eel of America, *Gymnotus electricus*, has only the external shape of an eel, and is in reality a very short fish, carrying very powerful electric organs in a long tail springing from a very short rump. A transverse section of the tail shows that a part of the muscle is changed into electric organs, while another remains unchanged.

In the different kinds of electric skates—*Torpedinidæ*—the electric organs are developed from muscles, which originally belong to the branchial arches and the arch of the lower jaw.

When we look to the nerve apparatus which enables the fish to throw the electric organs into action by a voluntary impulse, we find in every case wonderfully developed ganglion cells from which the impulse is transmitted directly to the electric batteries. Such a coincidence certainly cannot be the result of mere chance. But beyond the invariable presence of large ganglion cells as the starting points of electric nerve fibres there is very little uniformity in the arrangement of these elements in the different sorts of electrical fishes, on the contrary, there are most remarkable and striking differences not only in the position but also in the number and in the

FIG. 1.—Transverse section of the tail of *Mormyrus cyprinoides*.

FIG. 2.—Ganglion cells from roots of electric nerves of *Torpedo*.

the completeness with which such transformation can take place, I refer to the *Mormyrus*—the so-called pike of the Nile—a fish which has only of late been sufficiently known to possess electric power. A transverse section of the tail of any ordinary fish shows scarcely anything more than the vertebral column, muscles and their tendons, attached to the bones. On the other hand, a transverse section of the tail of *Mormyrus* (Fig. 1) shows no conspicuous muscles, but in place of them electric tissue filling up the entire space occupied by muscles in ordinary fishes. Of the muscular apparatus there is nothing left except the longitudinal tendons passing outside the electric organs from muscles placed anteriorly. If these tendons were cut across the *Mormyrus* would be unable to move its tail.

Omitting the complicated arrangement of histological elements in this modified muscular tissue in the different electrical fishes—which could not be sufficiently explained without a large number of illustrations—it may be sufficient to state that a kind of swelling loosens the molecular elements of the muscles and allows them to be settled again in a very regular but quite new form.

NO. 1212, VOL. 47]

appearance of these nerve centres. It is to be hoped therefore, that some important views regarding the character and functions of ganglion cells in general may be suggested by their study.

In the *Torpedo* the electric ganglion cells—being in vast numbers—form a bean-shaped mass in the medulla constituting the well-known electric lobe. It represents modified motor centres of the vagus nerve; anteriorly it is covered by the cerebellum, but emerging from beneath that organ, the lobe increases rapidly where the largest electric nerve leaves the medulla. Lower down its size again diminishes, where it gives rise to the fourth electric nerve and terminates quite free in a blunt point on each side. On counting the ganglion cells in a complete series of sections one finds the number to be about 54,000—a number that can be found to nearly correspond with the fibres in the electric nerves that arise from them. A transverse section of the medulla, close to the spot where the roots of the electric nerves are gathering, shows the so-called axis cylinder processes of the cells entering the roots to form the nerves. This is seen in Fig. 2—a photograph taken from nature like all the other illustrations of this paper.

Even the first and smallest of the electric nerves shows a great number of nerve fibres collected into bundles which on transverse section appear as if perforated by numerous small openings—each apparent aperture being a nerve fibre. I counted about 8039 fibres in the first electric nerve, in the second or largest about 23,770, in all four nerves about 58,318 fibres. This total exceeds that of the ganglion cells by at least 4000, but the disparity of number is probably to be accounted for by the impossibility of getting an exact total from a series of sections where the cells are very often dragged away by the knife.

The ganglion cells of the *Gymnotus*, or electric eel, are disposed in a different manner. Behind a short portion at the anterior end of the spinal cord where ordinary cells are found, the grey substance contains large rounded ganglion cells, the most anterior of them forming a semi-circle around the central canal of the cord. Since these first cells extend in front of the most anterior electric nerves, a transverse section of this region shows no axis cylinders leaving the grey substance, all being directed

electric nerves in the spinal cord, where the tail is endowed with the electric batteries, as seen in Fig 1. The cells are very soft, and must be very carefully preserved to show all their details. Their regular undivided axis cylinders leave the cord-like motor roots, and form a sort of plexus before leaving the vertebral canal. It is to be considered as a very important fact, that broad processes of the cells regularly intercommunicate on so large a scale that their union into a complete system for simultaneous action cannot be doubted.

Fig 3 shows such cells in the grey substance of the spinal cord; the intercommunicating processes can be seen much more distinctly in the microscopic slide and even in a photogram, than they appear in that figure.

The axis cylinder of each cell being a well-defined undivided process, the intercommunicating processes must be regarded as protoplasmic in the sense expressed by Deters. Their general intercommunication cannot have any other significance than to insure equality of action in giving the impulse to the electric batteries. If that statement be admitted the *protoplasmic processes of the cells must have a conducting function*.

If that be true in the *Mormyrus* there is no reason whatever why it should be otherwise in other vertebrates. Yet Golgi maintains that the protoplasmic processes of nerve cells are to be regarded as having a simply nutritive and therefore a non-nervous function.

There is another most remarkable fact in the organization of the *Mormyrus* having reference to the combined action of the electric organs on both sides. The upper as well as the lower electric nerves form a decussation outside the vertebral canal resembling the chiasma of the optic nerves. I am not acquainted with any other instance of motor nerves crossing the median plane to the other side of the body outside the cerebrospinal axis. In all other cases they are outside the brain and the spinal cord confined to their own side of the body to insure the isolated action of each muscle or group of muscles on that side. It is therefore stated that in changing the motor into an electric function these nerves at the same time became liberated from the strict rules of their predecessors. Certainly the case of *Mormyrus* gives a very good idea of the extraordinary power of adaptation to function with which Nature is endowed, but who can say how this particular anatomical arrangement could come about by gradual variation? I consider this difficulty far

greater than that relating to the first development of electric organs in general which is so frequently the subject of reference.

Since the celebrated investigations of Prof E. du Bois-Reymond have shown that the function of the muscular system is intimately associated with electric currents it is permissible to take them into account where muscle and their derivatives are under consideration.

I have shown elsewhere that most of the electric fishes are liable to a degeneration of the muscular system, seemingly caused—in part, at all events—by a certain lazy mode of life (disease of organs). We therefore find along with fully developed electric tissue in the *Gymnotus*, nests of muscles which have not arrived at perfection. In the *Mormyrus* degenerating muscles in the forepart of the electric organ suggest the impression that the process of transformation is still going on. Still more is this the case in the common *Raja*.

Moreover, we know that the peculiar degeneration of muscular tissue into electric tissue destroys the contractile power of the muscles, but does not interfere with their

FIG. 3.—Communicating Electric Cells in the Spinal Cord of *Mormyrus*

downwards to the gathering place of the first electric nerve roots, and therefore must be cut off. If, however, a transverse section be made in the middle portion of the cord the whole grey matter is seen to be packed with electric cells and their axis cylinders are seen passing very straight and undivided to join the electric nerve roots at once. The other processes of the cells are so pale and fine that it is impossible to recognize them sufficiently well in a complete section. Since the electric batteries extend along both sides of the tail to its very end, the electric nerves and their ganglionic centres have a similar extension. The electric cells form a continuous column in the spinal cord, but it is very slender, therefore, notwithstanding the great longitudinal extent of the electric centre, the number of cells is not so very great. I estimated the total number of cells to be about 60,000—not many more than the estimated number in the *Torpedo*.

The genus *Mormyrus*, whose electric power was doubted until quite recently, resembles the *Gymnotus* in the structural arrangement of its electric apparatus. I was fortunate enough to find the ganglion cells for the

electromotor properties, on the contrary the loosened and differently arranged elements of the changed muscles are more capable of producing electric currents. In that

FIG. 4.—Transverse section through the body of *Malapterurus* with a parasite in the electric organ.

state of development which has still quite an occasional character, it seems only necessary to assume that under certain favourable circumstances the fish while trying to catch a prey or to defend itself against an enemy in the sudden excitement becomes aware of its electric power hitherto unknown to itself. On perceiving the advantage of the electric power in the struggle of life the fish might begin to use it regularly and to develop it gradually to perfection in its descendants, just as a man might one day perceive that he is endowed with the power of hypnotism, consequently learns to use it and gradually improves it.

But now it is necessary to consider also the electric Shadfish of the Nile, the *Malapterurus electricus*, a powerful fish of very peculiar structure, which places it in quite a different category from the electric fishes already mentioned. A transverse section of the whole fish (Fig 4) shows the difference at once. The body of the animal is enveloped in a very thick electric skin, constituting one electric organ. Muscular tissue is nowhere deficient, other histological elements must therefore have furnished the material for the electric plates, which are packed very close in lozenge-shaped compartments of the skin.

In my opinion the plates are nothing else than modified cells of the cutaneous glands which are plentiful in the remainder of the skin. The precise proof of that statement ought to be furnished by a complete investigation of the development of the animal, which as yet is quite unknown. But the differences between the two kinds of electric organs are so great that we are surely entitled to separate the *muscular* from the *cutaneous* electric organs.

Assuming that the origin of these cutaneous batteries differs from those developed from muscle, we cannot wonder that their functions also differ in most important points. The electric current passes through the body in a direction the opposite of that in other electric fishes. There are *only two* electric nerve fibres, one on each side, which divide and subdivide until they give off more than two million branches. We shall see that these two nerve fibres are not true axis cylinder processes of

ganglion cells. Before making a more detailed reference to these interesting elements it may not be amiss to point out in the section shown in Fig 4 the existence of an intruder, a specimen of the so-called *Filaria piscium*, which had taken up its abode in the electric organ itself. This proves that animals can become accustomed to strong electric currents without receiving injury, and it suggests that the immunity of electric fishes against their own currents and that of their young *in utero* (*Torpedo*) is a faculty acquired by gradual training.

The construction of the single electric nerve fibre in *Malapterurus* resembles to a surprising extent that of an electric cable on a minute scale. We see the tiny nerve fibre like the central wire of the cable surrounded by a little non-conducting material and held *in situ* by a sort of network, the whole being enveloped in an enormous mass of connective tissue sheaths just like a cable protected externally by numerous layers of strong material. Fig 5 shows a transverse section of the central part only to render the details of the round fibre and supporting network more distinct. If we follow this single fibre inwards to its origin in the central nervous system we are led to a *single ganglion cell* from which the single fibre arises. There is one cell on each side of the cord, therefore just two cells in all, whereas in *Mormyrus*, which has the smallest number of electric cells in the fishes with electric organs of muscular origin, the cells must be estimated at more than 1500. The position of the two cells in the spinal cord of *Malapterurus* reminds one of Clarke's column in the cord of higher vertebrates where the cells differ in certain particulars from the motor cells. As already stated there is only one cell on each side, but

FIG. 5.—Transverse section of the central part of the electric nerve of *Malapterurus*.

that is a giant of its race. There is no real axis cylinder arising from the cell, but in place of it branched protoplasmic processes join and form a kind of perforated

plate beneath the cell, from which the nerve fibre starts with a broad base (Fig 6). I consider this a chief point of difference between this peculiar cell and all the other afore-mentioned cells of a motor character. Fig 6 gives a good idea of this magnificent histological specimen with its elegant nucleus showing its network and its nucleolus on one side.

Reviewing from a physiological standpoint the several facts stated above, we must feel convinced that the peculiar ganglion cells which are invariably found in relation to electric organs must play an essential part in bringing the electric organ into action. In my opinion that is tantamount to proof that other ganglion cells must be essential for sending nerve impulses to peripheral organs, and that the idea lately suggested by Nansen that ganglion cells have only a trophic influence on nerve tissue cannot be reasonably maintained in the face of these and similar facts. I may here refer to the well known peculiar ganglion cells found in the motor region of the brain of higher animals, including man. Betz, who discovered them, searched for them for the purpose of stating anatomically the laws of localization found by Prof. Hitzig and myself.

It may not be out of place to adduce here another piece of evidence taken from the department of pathology. My friend and collaborator Hitzig has lately published the case of a man who died from tetanic cramp of the head. He observed that in the ganglion cells of the motor centre of the fifth nerve presiding the affected muscles there was a very singular change to be observed *in these cells only*. It appears that the bacteria of tetanus caused a granular decomposition of the protoplasm in the cells, which led to a further state of degeneration characterized by the appearance of large holes, while the other ganglion cells and the remainder of the organ appeared quite healthy. I am convinced the case shows that the cramps in the combined muscles resulted from the irritation and gradual disorganization of the ganglion cells.

The above statements may suffice to show that the electric fishes and their nervous elements are really not such outsiders in science, and that the observations made on them should be brought into comparison and correspondence with those gathered from other sources. Indeed the histological elements in their organs are so instructive, that I would strongly recommend that the conclusions deducible from their study should be employed in maintaining well-founded former notions regarding the organization of the nervous system in vertebrates against certain revolutionary ideas of some modern authors.

GUSTAV FRITSCH

Physiological Institute, University of Berlin

#### AUSTRALIAN TRAVELS<sup>1</sup>

ON opening this work, one is at once struck by the beauty of the illustrations, particularly those of the New Zealand Alps. The double-page plate opposite p. 248, drawn from a photograph taken by the author, is especially worthy of remark. For effect this view may well compare with some of the most picturesque parts of Switzerland. Some of the photographs, however, have a familiar appearance to the travelled reader, one recognizes in the beautiful picture "Off the West Coast of Ceylon" (p. 300) an old friend, none the less worthy of reproduction.

<sup>1</sup> "Australische Reise," by R. von Lendenfeld, pp. 325, with illustrations. (Innsbruck: Wagner, 1892.)

The work makes no pretensions to a virgin freshness its professed object being to gather together the already published observations of the author, and to present them in a popular form. This it does very successfully, though the English reader could have dispensed with a good deal of the very apparent "padding." Thus the first twenty pages of this book of travel are devoted to the history of Australia, and remind one of Coghlan's opening chapter in the "Wealth and Progress of New South Wales," the next twelve pages on gold differ from Coghlan's second chapter, particularly in giving greater prominence to Count Strzelecki's discovery, and one regrets that no mention is made of James McBrien, who certainly ha

FIG. 6.—The right giant ganglion cell with the origin of its electric nerve from spinal cord of *Malapterurus*.

prior claims. The author is candid in his criticisms and condemns both the theatres and University of Sydney, as being, from the German standpoint, decidedly bad. On p. 34 we come to a "Journey into New South Wales," and here commences an interesting medley of natural history, traveller's tales, and geographical investigation. In this vacation ramble Von Lendenfeld claims to have discovered the culminating point of the Australian continent in Mount Townsend, to which he assigns (by aneroid) the height of 2241 metres. The doggerel verse on p. 82, in which a red sunset is taken to indicate approaching rain, must be wrong in its meteorology, so at least it proved, a red sunset being followed, much to Lendenfeld's surprise, by a fine day. It is satisfactory to find that the signs of the weather are not inverted at the Antipodes.

The author's familiarity with glaciers and ice-action in Europe served him in good stead in the southern hemisphere. Several interesting pages are devoted to his discovery of the former existence of glaciers in the Australian Alps, though there seem to have been contemporaries in this matter, for while Von Lendenfeld's observations proved the existence of *moutonnée* and striated surfaces down to a level of 1500 metres above the sea—Mr James Stirling claimed to have found signs of ice-action at lower levels still, as in the neighbourhood of Omaso, where they occur at 800 metres above sea-level. The historical conscience is strong in the author, or he would scarcely have troubled to recall the

fact, that when his communication on the discovery of glacial markings was read before the Geological Society of London, it was received with scepticism by Prof Bonney (and, let us add, though the author does not, by Dr Blandford also). On turning to the *Journal* of the Society we find that Prof Bonney considered the observations then adduced by Von Lendenfeld as insufficient to establish his conclusions, and in this opinion we fancy most geologists will be inclined to agree with him. That the conclusions were right after all is a different matter. It is to be regretted that even in this, his latest published summary, Von Lendenfeld does not always supply us with facts on which we can base an independent judgment. The personal opinion of an observer, however skilled, can be no sufficient substitute for these. A single instance will suffice. An important joint expedition was undertaken by the author and Mr Stirling to examine into the accuracy of the latter's statements as to the downward extension of the ice. After several pages of interesting traveller's gossip we reach the result in words much to the following effect—"After three-quarters of an hour's ride in the valley bottom we reached an old moraine, which we investigated closely. A dam 35 metres high and 200 broad composed of various (*verscheiden*) great blocks of rocks with sharp angles stretched across the valley. A brook flowed through the middle. We are here at a height of from 900 to 1000 metres, and since it is a veritable moraine Stirling is right and our dispute is ended."

We will not offend the susceptibilities of the author by questioning whether this is really a moraine. Probably it is, but no convincing proof of the fact appears in the description. One would like to know whether other signs of ice-action were observed in the immediate neighbourhood, in what respects the fragments differed from each other and from those of the adjacent valley slopes, and especially what evidence existed to show that they had been carried down the valley, and how far they are removed from their source. This information could have been conveyed in a few words, and would have been welcomed by inquiring minds, who now may wonder whether after all this dam could by any chance be merely the remains of an ancient landslip. New Zealand is introduced to us on p. 161, and after a short historical account we pass on to the New Zealand Alps and fjords. With regard to the latter the author stoutly maintains their glacial origin, one of his chief arguments resting on their great depth as compared with the sea into which they open. They are apparently submerged rock basins, but although the author may be right in his contention that they are not merely moraine-dammed valleys, yet he altogether overlooks another more probable explanation, depending on unequal subsidence. Submergence of the land has certainly taken place, and one has only to concede that the central mountain masses have sunk to a greater extent than the adjacent sea-floor to understand how the previously existing valleys would be converted into fjords. The greatest depth of Milford Sound is 360 metres, and one must travel (so our author tells us) at least 100 kilometres from the coast before this depth is reached at sea, now as the watershed is distant only 30 kilometres from the coast, it is at least as probable, considering the gradient, that we have to do here with differential movements of the land, as with locally concentrated erosive action.

An ingenious attempt to explain the last glacial episode leads to several bold generalizations. The author commences with the assertion that the whole of the southern hemisphere is at present much more severely glaciated than the northern, indeed he goes so far as to state that the northern hemisphere in the middle of the ice period was not much more severely glaciated than the southern is now. Since the mean temperature of the southern is not lower than that of the northern hemi-

sphere the reason for its excessive glaciation must lie in a more uniform climate and a damper atmosphere, and these again are a direct consequence of the greater extent of the oceanic surface.

Let us now suppose the sea-level in the northern hemisphere to rise 100 metres, the lowlands will become submerged (as during the last glacial episode they apparently were) the climatal conditions will then approach those now prevailing in the southern hemisphere, and excessive glaciation will result.

But in the southern hemisphere also, the ice was formerly of much greater extent, and this is not susceptible of the same explanation, since a depression of the land would not greatly affect the existing climate. What, however, would be the effect of a depression of the sea level? The submarine slopes of most of the land in the southern hemisphere are so steep that the present distribution of land and sea would not be largely modified, though the latter should sink 300 metres, on the other hand, the increase in the height of mountains (300 metres) would lead to a descent of the snow line, the growth of snow fields, and a corresponding enlargement of glaciers. Thus the glacial episode in the northern hemisphere might be attributed to an elevation of the sea-level, that in the southern to its depression, and these changes of level may have been produced by a bodily movement of the ocean waters from one hemisphere to the other, a result itself possibly due to a shifting of the centre of gravity of the earth. The author does not explain how to shift the centre of gravity of the earth.

We notice that the author speaks with disrespect of the maps of the Tasman glacier by Mr W. S. Green, stating that they are nothing like so good as Von Haast's, since however, later explorers prefer them to Von Lendenfeld's own, it would appear that we have here a descending scale of excellence.

After pointing out the failure of Mr Green to reach the actual summit of Mount Cook, the author gives a glowing account of a successful ascent of his own, not of Mount Cook however, but of the Hochstetter Dome. He therefore claims to be the first who has set foot on the top of a high mountain in New Zealand. We offer him our congratulations.

In commenting on the author's style, which in its lucidity is far more English than German, we must offer a serious protest against his manner of using what he terms our "transcendentally intense adjective." Bob Acres' remark that, "The best terms will grow obsolete. Damns have had their day," does not appear to apply to Australia, where, to judge from our author, they flourish along with other survivors of a Mesozoic age.

#### AMERICAN FORESTRY<sup>1</sup>

COMPETENT English authorities on forestry are so rare that no apology is needed for presenting some extracts from a translation from the German, of an important paper by Sir D. Brandis on American forestry. This is in continuation of a similar translation which appeared about a year ago in the columns of NATURE (vol. xlv p. 60).

Upwards of 1,000,000 acres of forest are required for the annual supply of wooden sleepers for European railways. These forests are properly managed so as to yield a steady return, whilst nothing of the kind can be said of American forests. This explains why German foresters are interested in watching the progress of forest destruction in America, where it is now merely a question of ten or

<sup>1</sup> "The Silva of North America." By C. S. Bergant, vols. i-iv. (Boston and New York: Houghton, Mifflin and Co., 1891-92.) Notes on the above by Sir D. Brandis, K.C.I.E., F.R.S., in *Zeitschrift für Forst und Jagdwissenschaft*, October, 1892.

fifteen years before a timber famine must occur, which will greatly enhance the value of European forests.

Brandis explains the present lamentable state of affairs in the United States, as follows.—The Timber Culture Act, which was in force in certain of the States, provided that settlers should plant up with trees one quarter of the area allotted to them, and it was thus hoped to obtain forests in the treeless regions between the Rocky Mountains and the Mississippi river. Large tracts of land have been occupied under this Act, but very little progress has been made in afforestation. It is not difficult in the Republic for people to neglect engagements they have made with the State. It has been recognized for some time past that this law has been practically of little use, and it was therefore abrogated in March, 1891. The law abrogating it, in section 24, empowered the President to demarcate and reserve certain tracts of State forest. Great hopes were therefore entertained, and soon afterwards a proclamation was issued largely extending the Yellowstone Park, in Montana, on the borders of Canada.

This measure had been strongly supported for some time past by the American Forestry Association. The Park is a mountain forest tract on the water-parting between the Rivers Columbia and Missouri, and its preservation and proper management is of immense importance. In October, 1891, the extensive forest tract in Colorado in the Rocky Mountains, in which several large tributaries of the Colorado river have their rise, and containing 1,365,000 acres, was proclaimed as the White River Forest Reserve. It was also expected that a portion of the western slopes of the Sierra Nevada, bordering on the Yosemite National Park, and other localities where the *Sequoia gigantea* flourishes, would be proclaimed as State reserves. These two national parks were previously reserved under older laws. The numerous intelligent friends of forestry in America confidently expected that a beginning would now be made in the demarcation of extensive State forest reserves, and in their scientific management.

The most recent news from America, however, has thoroughly upset these expectations. A Bill has been introduced into Congress, to hand over most of the Yellowstone forest reserve to a railway company. It is considered certain that this Bill will pass the Lower House, and it is not expected that the Senate will refuse to sanction it. Wood merchants, mining speculators, and sheep owners are vigorously agitating against the proposed reserve in the Sierra Nevada, and it is feared that their agitation will carry the day.

The American Forestry Association, which held its tenth annual meeting last January, has "memorialized" the President that instead of making a few reserves here and there, he should proclaim the reservation of all State forests still left to the Union, and arrange for their proper management. Friends of the forest are numerous in America, and insight into the essential necessity of forest protection is spreading, owing to the numbers of Americans who travel in Europe, but in a land where the dollar rules, and where an individual who will not recognize its authority is considered a fool, any steady progress towards State forest management cannot be expected.

Bernhard Fernow, the chief of the Forestry Branch of the Ministry of Agriculture at Washington, still hopes for action in this direction on the part of Congress and the State Executive. At the last meeting of the Forestry Association he rightly urged that æsthetic and sentimental grounds for improving American forests must be left entirely in the background. Only where important material interests are concerned, such as securing a continuous supply of wood, or a supply of water, or climatic considerations, should the State limit the freedom of its citizens in dealing with forests. If, however, for urgent reasons of public utility, it should be necessary to reserve

a forest, the State should not be contented with merely demarcating and protecting it, but should introduce scientific management, so that the neighbouring populations may be able to utilize the forest produce, and in any case, all pre-existing rights acquired by the people in the forests should be strictly protected. Fernow concludes with the strongly-expressed advice that a law should be passed reserving the relics of the forests of the Union, and preventing any fresh alienations. He firmly believes that such a law is most urgently required. It is, however, quite a different matter for Congress to pass any such law, though more may perhaps be expected from the separate States in the Union, and in those of New York and California some rather halting steps have been taken in the right direction.

As matters stand at present in the United States, it is pretty obvious that a time will come when landowners will look upon their private forests as a good investment, for prices of wood and other forest produce are steadily rising. Little progress has, however, yet been made in this direction, and recent attempts made by some rich men to manage their forests properly with advantage have failed.

Sir Dietrich Brandis then turns to the progress made in the study of American forest trees, and states that literature on the subject is pretty abundant, but is after all merely thrashing straw. What is wanted in America is a practical proof that in forests of the Weymouth pine, of Minnesota, or of Californian red wood, or of Douglas fir in Washington and Oregon, or in the splendid mixed broad-leaved forests of the Alleghany mountains, good forest management will prove more remunerative than wasteful pillage (*Raubbau*).

The remainder of Brandis's paper is chiefly of botanical interest, and greatly praises Sergeant's magnificent work. One other passage is too interesting to be omitted. It refers to the mesquit tree, *Prosopis juliflora*, which belongs to the dry zone in the south west of the United States, and is also found in Mexico, and in the Andes as far as Chili and Argentina. In the river valleys of Arizona, where, although the air is dry, yet subsoil water is near the surface of the ground, this species forms extensive forests. On drier soils the aerial parts of the tree are reduced, but the root system is greatly extended. Sergeant states that while the stem may be only a few inches high, and may only bear a few leaves, yet the tap root goes straight down to the subsoil water, and the aerial growth of the tree furnishes a clear indication of the depth at which the latter may be found.

Wherever the mesquit is a tree the subsoil water is forty to fifty feet down, where it is a small shrub it is from fifty to sixty feet down, and wherever the roots descend over sixty feet, the plant is not more than two or three feet high. In the scantily-wooded districts, where the mesquit tree grows, its roots yield most of the firewood, and are dug up, or dragged by oxen from the ground. *Prosopis spicijera* in the drier parts of India similarly furnishes fuel and cattle fodder in the Punjab, Sindh, and parts of Berar. This tree, there termed the *Jhand*, sends down its roots to a depth of fifty feet and more, to the subsoil water, and thus produces wood in a dry country, providing the peasant with fuel and wood for his plough.

W. R. FISHER.

#### JOHN STRONG NEWBERRY

IT is not only in the United States that the death of this veteran of scientific research will bring widespread regret. To many geologists and palæontologists in this country and on the Continent he was personally known, and those whom he honoured with his friendship will feel keenly the loss they now sustain. He was born at New Windsor, Connecticut, on December 22, 1822,

and took the degree of M.D. from the Cleveland Medical College, Ohio, in 1848. Before beginning the practice of medicine, which he intended to be his occupation in life, he spent two years in Europe. During his stay at that time in Paris he acquired a good knowledge of the French language, and had many opportunities of cultivating a love of science, which soon manifested itself as one of his distinguishing characteristics. Returning to his native country, he began practice as a medical man at Cleveland in 1851. Even at the outset of his professional work he contrived to find time also for scientific enquiry. His first published paper appeared in the same year in which he started in his medical profession. It is devoted to the geographical distribution of land and fresh-water shells.

But he soon entered upon the two branches of geological investigation in which he was to make his name familiar all over the civilized world—the study of fossil botany and of fossil fishes. As early as the year 1853 he made his first contribution to the history of Carboniferous plants, and three years later his earliest memoir on fossil fishes was published. By this time his scientific acquirements and enthusiasm were widely known. Hence when an expedition under Lieutenant Ives was organized for the exploration of the Colorado River of the West, Newberry was selected to accompany it, and to take charge of the observations to be made in natural history. His geological contribution to the famous Report at once placed him in the very front rank of American geology. His account of the geological structure of the region traversed by the expedition, and of the marvellous denudation of the cañons, will always remain as one of the landmarks of geological progress.

He had now been touched by the fascination of exploration in the far west. The drudgery of medical practice became irksome to him, so that when in the year following his return from Colorado the offer was made to him to take part in another expedition, he gladly availed himself of the opportunity. He accordingly accompanied Captain Macomb in an exploring expedition in the summer of 1859, from Santa Fé, New Mexico, to the junction of the Grand and Green Rivers of the Grand Colorado. This journey forms the subject of another masterly report by him, which, however, was not published for some sixteen years.

The shadows of the coming great Civil War were already falling on the United States, when Newberry was at work on the preparation of the record of the results of his western journeys. The storm at last burst in 1861, the same year in which his Colorado report was issued. Among the many scientific men who placed their services at the disposal of the North, Newberry took a foremost place. His medical skill and wide general scientific knowledge enabled him to be of great use to the army. He specially distinguished himself in the organization and administration of the hospital department. Among the reminiscences of his not uneventful life he had many graphic tales to tell of his experiences during that momentous epoch in the history of the United States. After the close of the war in 1865 he returned with renewed ardour to his scientific labours, and specially devoted his energies to the study of the ancient floras and fish-faunas of North America. Among his numerous memoirs on these subjects the two large monographs forming vols. xiv and xvi of the series published by the United States Geological Survey are specially worthy of notice. But they represent only a part of the enormous mass of material which he had worked over.

Prof Newberry early in his career saw how great was the aid which geology could afford in the development of the mineral industries of his native country, and he gave himself with great energy to the practical applications of the science. He became one of the highest authorities on mining matters in the country,

and he was mainly instrumental in the equipment of the great mining school of Columbia College, New York. He occupied the Chair of Geology in that establishment, and threw himself heart and soul into its duties. At last, in the midst of his work and honours, a stroke of paralysis disabled him from active duties, and he grew gradually feebler until his death. With him American science loses one of its most honoured and distinguished cultivators. His piercing eyes and well-cut features made him a marked figure in any assembly, while his courtesy and gentleness, and his unfailing helpfulness and serenity, gave him a charm which will endear his memory to a wide circle of friends. A G

### NOTES

ALL entomologists in the country will learn with great satisfaction that the Treasury has consented, on the recommendation of the Trustees of the British Museum, to make provision in the estimates for the coming financial year for the purchase of Mr Pascoe's well known collection of insects. The importance of the acquisition of this collection by the nation is very great, as it contains an immense number of types, especially of the families Longicornes and Curculionides, to which Mr Pascoe devoted so much attention for a period of more than forty years. Its dispersal or removal to a foreign country would have been an irreparable loss to British entomologists.

THE medals and funds to be given at the anniversary meeting of the Geological Society of London on February 17 next have been awarded as follows. The Wollaston Medal to Prof N S Maskelyne, F.R.S., the Murchison Medal to the Rev O Fisher, the Lyell Medal to Mr F T Newton, and the Bigsby Medal to Prof W J Sollas, F.R.S., the balance of the proceeds of the Wollaston fund to Mr J G Goodchild, that of the Murchison fund to Mr G J Williams, and that of the Lyell fund to Miss C A Raisin and Mr A. Leeds.

BETWEEN June 10 and 18 the University of Montpellier will celebrate the third centenary of the foundation of its Botanic Garden, on which occasion it is intended to invite a general congress of the botanists of all nations.

A MEETING of the Association for the Improvement of Geometrical Teaching was held on January 14, at University College, Gower Street, the chair being taken by the Master of St John's College, Cambridge. The reports of the Council and treasurer having been read and adopted, Dr Wormell was elected President for 1893, the hon. secretaries (Mr E M Langley, 16, Adelaide Square, Bedford, and Mr C Pendelbury, 4, Glazbury Road, W Kensington), and the other members of the Council being re-elected. Dr. Wormell having taken the chair, Mrs Bryant gave a model lesson on geometry to a class of about twenty ladies. After an adjournment papers were read by Mr G Heppel on the use of history in teaching mathematics, and by Mr F E Marshall on the teaching of elementary arithmetic. The attendance was larger than usual, and interesting discussions followed the lesson and the papers.

A DEPARTMENTAL committee, consisting of officers of the Charity Commission, the Education Department, and the Department of Science and Art has been appointed by Mr Acland, Vice-President of the Committee of Council on Education, to consider the question of the organization of secondary education in England and Wales, and the relation of the Departments among themselves in connection with this subject. The Committee consists of the following members.—The Vice-President of the Council (chairman), Sir H Longley, K.C.B., Chief Charity Commissioner, Mr T E Ellis, M.P., Parliamentary Charity Commissioner, and Mr Fearon, Secretary to the

Charity Commissioners, representing the Charity Commission, Mr Kekewich, C B, Secretary to the Committee of Council on Education, and the Rev T W Sharpe, her Majesty's Senior Chief Inspector of Schools, representing the Education Department, and Major General Donnelly, C B, Secretary of the Department of Science and Art, Captain Abney, C B, F R S, Assistant Director for Science, and Mr Armstrong, Director for Art, representing the Department of Science and Art, Mr H W Simpkinson, Examiner in the Education Department, acts as Secretary to the Committee

ON the 25th inst an influential deputation will wait upon the President of the Board of Trade to urge the adoption of the decimal system of coinage and weights and measures in Great Britain Among those who propose to form part of the deputation are the Agents General for Victoria, Queensland, and the Cape, and several prominent members of the various chambers of commerce

THE Infant University of Chicago seems to be resolved to arrange its staff of teachers on a scale commensurate with the size of the North American Continent Thus, the Department of Geology is placed in the hands of no fewer than seven distinct professors and two assistant professors, each taking some special branch of this wide science under the competent leadership of Prof T C Chamberlin Three of the professors are non-resident, but they will probably give occasional lectures, and will at least direct the studies in their own branches of research

MR JOHN D ROCKEFELLER, who had already presented the University of Chicago with 2,600,000 dollars, has now given it another million The university owns land, buildings, and other property valued at £1,400,000 sterling, and the principal is ambitious enough to hope that in course of time it may have "such an array of magnificent buildings as one sees at Oxford or Cambridge"

A BOTANICAL laboratory has been established at Eustis, Lake Co, Florida, chiefly for the investigation of diseases of the orange and other species of *Citrus*, under the direction of Prof W T Swingle The anatomy, physiology, and pathology of other sub tropical economic plants will also be investigated

ON Saturday last Prof Flinders Petrie delivered his first lecture as professor of Egyptology at University College, Gower Street In the course of the lecture he said that, besides more than a thousand photographs and various impressions or "squeezees" of sculpture, a collection of original objects would be exhibited for the close examination of students Miss Edwards had formed a collection with much care—as complete and typical as possible He hoped also to place on loan his own collection, and to have a series of annual loan exhibitions drawn from the many valuable private collections in England There would thus be found a collection of deities, the most complete collection of scarabs, the only chronological collection of beads, a dated series of pottery, the largest collection of funeral cones, and also of Egyptian weights In certain lines of study their museum would not be merely supplemental, but would be in advance of any historical museums He proposed to give a series of lectures in the autumn and spring, and would prepare students who might wish to undertake practical work in Egypt, where he would spend the time before Christmas to Easter

MR ROWLAND WARD is exhibiting in his studio a valuable collection of African trophies and curiosities, most of which have been brought to England by Captain Lugard and Mr F C Selous Besides natural history specimens, the collection includes many weapons and products of native art.

ANOTHER severe loss has been sustained by science in Russia through the death of the well-known mineralogist, Nikolai Ivanovitch Koksharoff He died at St Petersburg on January 2 He was born on December 2, 1818, in West Siberia, in a village near which at that time was the fort of Ust Kamenogorsk, and he made his studies in the Mining Institute at St Petersburg In 1841, when he was a mining engineer in the Urals, he accompanied Murchison on his journey to Russia and to the Urals, and the intercourse with the great geologist led him to adopt a scientific career He spent the next three years studying in Western Europe, and on his return he devoted himself entirely to mineralogy, and especially to goniometric measurements of minerals, in which he was so much aided by his wife that his numerous writings on this subject are as much her work as his He lectured in his early years on geology and physical geography, but later on devoted himself almost entirely to the description of Russian minerals, of which he discovered and described many new ones His chief works are embodied in eleven large quarto volumes of "Beiträge zur Mineralogie Russlands," illustrated with numerous plates The twelfth volume was in type when he died In 1866 he was made a member of the St Petersburg Academy of Sciences, and many scientific bodies of Western Europe elected him corresponding or honorary member

DURING the past week the weather has been of a very unsettled character, at first an anticyclone lay over the greater part of these islands, while areas of low pressure were situated over the North Sea and to the west of Norway With these conditions the weather became warmer in this country, the daily maxima varying from 40° to 46°, but over the Continent very low temperatures continued to be registered, the minima in Sweden varying from 60° to 65° below the freezing point, while exceptionally severe weather also prevailed over France and Germany On Sunday a depression was passing to the southward of these islands, and under its influence north-easterly gales were experienced in the eastern and southern parts of England, a sharp frost occurred over this country, accompanied by snow in most parts, while a thaw set in over Scotland and rapidly spread southwards, accompanied by rain, the maximum temperatures reaching from 45° to 50° Subsequently the conditions were again becoming anticyclonic, accompanied by a return of colder weather, but they were not at all settled, snow was falling on Tuesday in the south of England For the week ending the 14th instant the temperature was everywhere below the mean, the deficit ranging from 2° to 5° The amount of bright sunshine exceeded the average in the north and west of Scotland and in the south-west of England, elsewhere the amount recorded was very small, being only 3 per cent in the north west of England

Das Wetter of December last contains an account of a heavy thunderstorm which occurred at Paderborn on August 9, 1892, in which a number of living pond mussels were mixed with the rain The observer who is in connection with the Berlin Meteorological Office sent a detailed account of the strange occurrence, and a specimen was forwarded to the Museum at Berlin, which stated that it was the *Anodonta anatina* (L.) A yellowish cloud attracted the attention of several people, both from its colour and the rapidity of its motion, when suddenly it burst, a torrential rain fell with a rattling sound, and immediately afterwards the pavement was found to be covered with hundreds of the mussels Further details will be published in the reports of the Berlin Office, but the only possible explanation seems to be that the water of a river in the neighbourhood was drawn up by a passing tornado, and afterwards deposited its living burden at the place in question.

Mr C. F. MAXWELL writes to *Science* from Dublin, Texas, that on the night of November 29, about 8 o'clock, a very large meteor was seen passing westward, a little to the south of that place. Just as it seemed to be passing the body exploded, producing a sound that was distinctly heard, resembling that of a rocket explosion or a pistol-shot. After the explosion a body half as large as a full moon moved away to the westward, making a hissing or frying sound. Mr Maxwell has seen no one who saw the meteor before the explosion. The whole country was brilliantly lighted for a moment as if by a continued electric discharge, but at the time of the explosion the light was red and blue, or perhaps violet. The sound of the explosion was heard by parties five miles west and seven miles east of Dublin, who could not have been less than ten miles apart on an air-line, and they report the sound together with the other phenomena to have been about the same as they were at Dublin.

WHEN commanding the *Narade* during the cyclone of November 6, 1891, Rear Admiral Cavalier de Cuverville had the opportunity of testing the efficiency of oil in calming the troubled waves of the North Atlantic. The last number of the *Revue Maritime* contains an account of his experiences and conclusions. When the waves threatened to become dangerous he gave orders to fill two coal sacks with tow steeped in oil, one of them to be suspended freely at the extremity of a spar spanned to the cat-head, the other near the bridge. The effect was excellent. No seas were shipped, and the vessel escaped without breaking a spar. It appears that the oil takes effect upon the "breakers" due to horizontal translation produced by the wind, leaving the orbital motion or "swell" unaffected. The former is the only element of danger in a rough sea. It was found that two sacks, filled with 5 kgr of tow, holding 5 litres of colza or machine oil each, were sufficient to protect a vessel 75 m long. The oil had to be renewed every six hours. Too much oil has the disadvantage of spreading more slowly, and theoretically the best system of distribution would be one in which the oil would reach the surface from below in a large number of small drops.

HERR J. NAUE has been fortunate enough to discover at a prehistoric station near Schaffhausen a piece of limestone, on both sides of which are drawings like those which have been found in caves in France and in the cave at Thayngen. It was found in the lowest part of the yellow "Kulturachicht" among bones and teeth of reindeer, horses, and other animals. On one side are a horse, a foal, and a reindeer, while several horses appear on the other. The style is not so fine as that of the Thayngen drawings, but, according to Herr Naue, they display a power of keen observation, and he points out that it was more difficult to work on stone than on a bone still fresh.

THE remarkable address delivered by Prof. Virchow on his assumption of the office of Rector of the University of Berlin has been issued by the German publisher, August Hirschwald, of that city. The title is "Lernen und Forschen."

THE *Pharmaceutical Journal* of the present week prints the first of what promises to be a good series of papers, which are intended to make bacteriology intelligible and interesting to students, and to be of some practical value to pharmacists in business. The *Journal* rightly thinks that the time has come when pharmacists ought to make themselves familiar with the principles of "this newest department of experimental science."

LAST week Lord Kelvin delivered an interesting speech at a dinner given to the members of the new watch factory at Prescott. He said it was something to be proud of that the article they were making was a triumph of mechanism. There

was nothing in the whole of scientific art, nothing in the results of mechanics applied to the useful purposes for mankind, that was a more splendid success than the science of watchmaking. He had been all his life engaged more or less with scientific experiments, with measurements, and with instruments which their French friends would call instruments of precision. They knew something of instruments of precision in electricity, and they were thankful if they could make a measurement which was accurate to one-tenth or one-twentieth per cent. But what did watchmaking do? The commonest cheap watch—cheap but good—which would issue from the Prescott works would keep time to a minute a week. Now a minute a week, if they made a little calculation, was something like one-hundredth per cent of accuracy, or just about ten times as accurate as they considered exceedingly good work in electrical measurements.

AT a recent meeting of the College of Preceptors, Mr. Foster Watson read a remarkably interesting paper on Richard Mulcaster, who was head-master of St. Paul's School from 1596 to 1598. The paper is printed in the current number of the *Educational Times*. Mulcaster's ideas were in some respects far ahead of those of his time. The following, according to Mr. Watson, were his "main educational contentions"—(1) Culture and learning for those who have the wit to profit by it, whether rich or poor. Adequate knowledge for those who go into trade. (2) Education for girls and women, as well as boys and men. Higher education for girls who have good abilities. (3) Training colleges for teachers. (4) Physical training for all—boys and girls, teachers and pupils, and this to be continued in after life. (5) Liberal education, with disinterested aims for the elementary schools. (6) The best masters to take the lowest classes. (7) Drawing and music to be taught in every school, not as "extras," but as essentials. "You will notice," says Mr. Watson, "that the last named five aims are only within the field of discussion even yet, they are not *faits accomplis*. All this time they have been in Mulcaster's book, and Mulcaster's book—a few copies of it, very few—have been gathering dust."

THE Association of Officers of Colleges in New England have recommended the gradual adoption of the following changes in the curriculum of New England grammar schools—(1) The introduction of elementary natural history into the earlier years of the programme as a substantial subject, to be taught by demonstrations and practical exercises rather than from books. (2) The introduction of elementary physics into the later years of the programme as a substantial subject, to be taught by the experimental or laboratory method, and to include exact weighing and measuring by the pupils themselves. (3) The introduction of elementary algebra at an age not later than twelve years. (4) The introduction of elementary plane geometry at an age not later than thirteen years. (5) The offering of opportunity to study French, or German, or Latin, or any two of these languages from and after the age of ten years. (6) The increase of attention in all class-room exercises in every study to the correct and facile use of the English language. In order to make room in the programme for these new subjects, the association recommends that the time allotted to arithmetic, geography, and English grammar be reduced to whatever extent may be necessary. The association explains that it makes these recommendations in the interest of the public school system as a whole, but that most of them are offered more particularly in the interest of those children whose education is not to be continued beyond the grammar school.

MR. WALDO DENNIS gives in *Science* a minute and very interesting account of a snake which he watched for an hour in the woods one morning in July last. It went straight up a tree "without crook or turn," and by and by lay still for a while,

basking in the sun Mr Dennis notes that while in this position it lifted up its head four or five inches and gaped. Its mouth opened very wide; and when the mouth was closing, the nervous spasm, only half expended, again seized upon the jaws, whereupon they went wider than before, the spasm exhausting itself at last in a parting wriggle or two to the head. "So natural," says Mr Dennis, "was this novel performance, that I involuntarily listened for that characteristic accompaniment, the little agonizing whine so common with the dog, and and not uncommon with us."

Few things are more frequently said than that diseases of the nervous system, especially those of a hysterical character, have increased with the growth of civilization. Dr de la Tourette has been trying to show, in the *Journal de Médecine*, that this is an error, and Dr D. G. Brinton, in *Science*, expresses cordial agreement with him. Travellers who give the soundest information on the subject, says Dr Brinton, report that in uncultivated nations violent and epidemic nervous seizures are very common. Castrén describes them among the Sibiric tribes. An unexpected blow on the outside of a tent will throw its occupants into spasms. The early Jesuit missionaries paint extraordinary pictures of epidemic nervous maladies among the Iroquois and Hurons. During the Middle Ages there were scenes of this kind which are impossible to day.

THE question as to whether electrification is produced by the friction of gases has been exhaustively dealt with by Mr. Wesendonck, who gives an account of his results in *Wiedemann's Annalen*. The apparatus resembled that employed by Faraday with negative results, in the case of dry air. Mr Wesendonck used air compressed to 100 atmospheres in Elkan steel bombs of 1000 litre capacity. This was passed through a brass tube widening out into a cone into which a similar cone could be screwed from the opposite direction, so as to leave a conical path for the air issuing from the bomb. The second cone was connected to a delicate electrometer, which indicated any electrification produced by the impact of the air. Ordinary air was thus found to give considerable negative charges, up to  $1\frac{1}{2}$  volt, if the cones were far apart, and positive charges if they were screwed up close. But no electrification was produced when the air had been previously freed from dust and moisture. Oxygen behaved in the same way. Carbonic acid, evaporated from the liquid state, imparted a strong positive charge to the brass, which was, however, reversed as soon as the cold led to the precipitation of water vapour. Ordinary atmospheric dust was found to electrify the brass negatively, the charge being increased by previous drying. It seems, therefore, that pure gases are incapable of producing electrification by friction, and that the effects observed are conditioned by the presence of minute solid or liquid particles.

FISHES in badly-ventilated aquaria give various signs of oppression, such as restlessness, frequent gasping, mounting to the surface, leaping into the air, &c. Experiments have been recently made by Messrs. Duncan and Hoppe-Seyler (*Zeitschrift für Phys. Chemie*) to ascertain to what point the oxygen-content of the water may be lowered before fishes indicate uneasiness. They were made with tench, trout, and crayfish in an elliptical glass vessel, with pipes for injecting and removing water and air, &c., in one case a pipe communicating with a chamber in which was a live rabbit, conveyed to the fishes air impoverished by the latter's breathing, while the behaviour of rabbits and fishes in the same air could be compared. With 4 to 3 cubic centimetres O in the litre of water, the fishes seemed well and content, and with the corresponding O tension in the air (8 to 11 volume-percentage) the rabbit was in no difficulty. With 1.7 to 0.8 cubic centimetres O in the water, the trout were evidently ill at ease, and, if it continued, they died. The tench

and crayfish, however, stood still further reductions, the former finding relief at the surface. Reduction of the O to zero soon produced the worst symptoms.

It was long ago shown by Sir J. B. Lawes that plants on ground that has been long without manure evaporate more water than those on good ground. Further research has proved that transpiration is not proportional to leafy development, for it largely depends on the activity of the roots, as well as evaporative surface. M. Dehérain has lately (*Ann. Agr.*) been led to investigate the influence of manure on the development of roots; and he finds that roots in unmanured ground have a much larger growth than in manured, having to spread more in search of the scanty nutriment. If, then, a plant with small leafy growth, evaporates more water relatively than one with large, it is probably due to large root-growth procuring more water. The observation of Volkens is cited, that desert plants have extraordinarily long roots. Further, M. Dehérain points out, the solar rays falling on a plant have a twofold work to do, viz assimilation and transpiration. And these are complementary. In strong leafy plants there is vigorous assimilation, so that transpiration is limited, while in the leaves (with little chlorophyll) of an "anæmic" plant a larger fraction of the solar energy is given to transpiration.

In the *American Geologist* an account is given of a preliminary examination of some specimens of a coally mineral, having the general properties of a cannell, from the Kootenai and Lower Cretaceous of British Columbia. Their examination was of more than ordinary interest on account of their peculiar physical constitution and the great difficulty of ascertaining their connection with any of the materials ordinarily known to contribute to coal formation. The main characteristics of the mineral are the total absence of structure, and the presence of tubular ramuli resembling fungus mycelia, as well as rounded cavities. Angular fragments of material of the same nature as the larger rod-like bodies appear in the sections, and an amorphous substance either occurring in distinct flakes or acting as a cement to unite the rods. Mr Penhallow's examination has made it probable that the origin of these coals must be sought in some other direction than modified vegetable structure. It is suggested that they represent a form of fossil resin accumulated during a period when resin-bearing trees were very abundant, and possessed a structure favouring the rapid disintegration of organic tissue.

A YOUNG lady in America seems to have the power of awakening not only the intelligence but the affections of insects. Her experiences are recorded in *Science* by a friend of hers, who signs himself "B." In September some one gave her a beetle, which is described as a specimen of *Pelidnota punctata* Linn. At first she kept it in a small box, feeding it with grass, leaves, and small pieces of fruit, such as peaches, pears, &c. Occasionally she would give it a drop of water to sip. It would sometimes bite a little out of a leaf, would eat the fruits, and would take water eagerly. From the first she would take the insect in her fingers several times a day and stroke or caress it, also putting it to her lips and talking to it all the while she handled it. When she put it to her lips it would brush its antennæ over them with a gentle, caressing motion. When she left her room she would shut it up in its box. One day, about two weeks after she received it, she was called out suddenly and neglected this precaution. She was absent for some time, and when she returned the insect was not in its box nor anywhere to be seen. Fearing that she might injure it, she stood still and called "Buggie, buggie," when it came crawling from its retreat towards her. "After this," says "B.," "she would frequently leave it free in the room when she went out, and when she returned, if the insect was not in sight, she would

call it, and it would crawl or fly to her. As this was continued, it would more and more frequently fly to her instead of crawling, until at last it flew nearly every time it was called. When it came in this way she would put it to her lips or to her nose, and the insect would appear to be pleased, moving its antennæ gently over her lips, or taking the end of her nose between them and touching it with a patting motion. Unfortunately this interesting beetle lost its liveliness in winter. It was placed on a cloth above the kitchen boiler, where it revived to some extent, but in December it accidentally fell to the floor and soon afterwards died.

THE annual report of the U.S. Commission of Patents for the year 1891 has been issued. In addition to the usual statistical information there are added to this report two tables and two diagrams illustrative of the growth of patent-granting from 1790 to 1890, the first century of the existence of the American patent system. The first table gives the patents granted in that period by years and by States to American citizens. The second table does the same for patents granted to citizens of foreign countries. The first diagram has one line illustrating graphically the growth of patent-granting during the century, along with another line denoting the increase of population in the same period. The second diagram has one line illustrating the growth per capita of patent-granting as a whole during the century, and other lines illustrating the growth per capita of patent-granting in the States by groups of States. There is also a list of patentees and their improvements, by years, prior to the year 1800.

THE first volume of the *Irish Naturalist*, a monthly journal of general Irish natural history, has just been published, and a very interesting volume it is. The editors are Mr. G. H. Carpenter and Mr. R. Lloyd Praeger, and they have secured from able contributors many good articles on subjects which cannot fail to be attractive to Irish readers. The volume also records work done by some of the foremost of the Irish scientific societies.

THE Bureau des Longitudes has issued, through Messrs. Gauthier-Villars et Fils, its "Annuaire" for the year 1893. It contains, as usual, a great mass of scientific information, clearly arranged. Among its "notices" is an interesting paper upon the observatory of Mont Blanc, by M. J. Janssen.

THE Belgian Royal Academy of Science, Letters, and Art has also issued its "Annuaire." Among the contents is a rather elaborate memoir of Jean Servais Stas, accompanied by an excellent portrait.

MESSRS. CHARLES GRIFFIN AND CO. have published a ninth edition of "A Pocket Book of Electrical Rules and Tables for the Use of Electricians and Engineers," by John Munro and Andrew Jamieson. The authors state that the work has been carefully revised and enriched with fresh matter, including several important communications by leading authorities on electro-technics.

MESSRS. GEORGE BELL AND SONS have issued the first portion of a supplement to the third edition of "English Botany, or Coloured Figures of British Plants." This part has been prepared by Mr. N. E. Brown. The rest will be done by Mr. Arthur Bennett.

In our review of "Modern Mechanism" last week (p. 242) a typical American express locomotive with 20 x 24 cylinders was said to be less powerful than an 18 x 26 cylinder British engine. This should, of course, be reversed, the American engines being the more powerful.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ?) from India, presented by Mr. F. Skinner, eleven Tuatera Lizards (*Sphenodon punctatus*) from Stephen's Island, Cook's Straits, New Zealand, presented by Captain E. A. Findlay, a Puff Adder (*Vipera arulans*) from East Africa, presented by the Directors of the British East African Company, a Vulpine Phalanger (*Phalangista vulpina*), from Australia; a Stanleyan Chevrotain (*Tragulus stanleyanus* ♂) from Java, deposited, a Sanderling (*Calidris arnaria*), European, two Brown Capuchins (*Cebus fatuellus*), an Azara's Fox (*Canis azara*), a Ring-tailed Coati (*Nasua rufa*), seven Glossy Ibises (*Plegadis falcinellus*), a Brown Milvago (*Milvago chimango*), four Barn Owls (*Strix flammea*), a Ypecaba Rail (*Aramides ypecaba*), a Chilean Pintail (*Dafila spincanda*), a Geoffroy's Terrapin (*Platemys geoffroyana*) from South America, purchased, a Hog Deer (*Cervus porcinus*), born in the Gardens.

### OUR ASTRONOMICAL COLUMN

COMET HOLMES.—The following tele gram was received from Dr. Copeland on Tuesday evening—"Comet Holmes reported suddenly brighter. Stellar" (nucleus). We therefore continue the ephemeris (Schulhof, for Paris, midnight).

Date	RA app.	Decl app
	h m s	° ' "
Jan. 19 ..	1 25 53.2	+33 39
20	27 13 7	39
21	28 35 1	39
22	29 57 2	39
23	31 20 1	40
24	32 43 7	40
25	34 8 0	41
26	1 35 33.0	+33 42

The comet is now almost midway between  $\beta$  Andromedæ and a Trianguli.

BURNHAM'S DOUBLE-STAR OBSERVATIONS.—Mr. Burnham's splendid series of double star measures, made chiefly with the 3 foot refractor at the Lick Observatory during the first six months of 1892, are published in *Ast. Nach.* No. 3141. He states that the superiority of the great telescope for this work has been fully demonstrated. In the present list there are micrometric measures of eight new double stars, and additional measures of 170 old ones.  $\chi$  Pegasi has completed more than one revolution since its discovery in 1880, the period being about eleven and a half years, which "is probably shorter than that of any other known pair in the heavens."

Mr. Burnham's connection with the Lick Observatory having permanently ended in June last, the present list of measures concludes his work on double stars. It is to be hoped that the field of work which he has so brilliantly occupied will not be neglected in the future.

EPHEMERIS OF COMET BROOKS.—The following is a continuation of Kreutz's ephemeris for Berlin, midnight.—

Date	RA (app.)	Decl. (app.)	Log r	Log $\Delta$

THE ECLIPSE OF APRIL 16, 1893.—In a communication to the Astronomical Society of France, M. de la Baume Pluvinel indicates some of the points to which attention should be directed in the eclipse of the sun in April. In the first place, he does not think any of the precious moments of totality need be devoted to the study of prominences, as these can now be completely studied at any time. The investigation of the corona is all-important, and attempts should be made to obtain photographs showing its general aspect with various exposures, as well as photographs of its spectrum. The different parts of

the corona are of such varying brightness that it will be impossible to obtain all the details with a single exposure. For the spectroscopic work it is also recommended that isochromatic plates be employed, with special reference to the distribution of the material which gives the green line 1474 Kirchhoff. Mr. Lockyer proposes to use an objective prism, so as to obtain monochromatic images of the corona, that is, rings corresponding to each elementary radiation of the coronal light. This method will not only give the spectrum of the corona, but the distribution of each spectrum line over the whole of it. The problem of the "reversing layer" is also wanting definite solution, and it is pointed out that instantaneous photographs may settle the question once for all. M. Pluvinel also points out the importance of noting the presence or absence of the hydrocarbon bands suspected by Tacchini in 1883, as this observation may throw further light on the analogy between the corona and the tails of comets.

Photometric observations should also be secured, and the polariscope should be employed to determine the proportion of polarized light in various parts of the corona.

**NOVA AURIGÆ**—Prof. Barnard has recently made some measures of the position of Nova Aurigæ, with a view to detecting proper motion. The two comparison stars selected were the stars E and F in Mr. Burnham's previous list of comparison stars. The results are stated thus (*Ast. Nach.* No. 3143)—"The measures with F come out identical with Mr. Burnham's during February, but those with E seem to show some sort of motion in distance and possibly in angle. From the position of the comparison star this can hardly be due to parallax. It is possible, though, if the discrepancy is a real displacement, that it is due to orbital motion, the orbit being so situated as to show no motion with reference to F. The difference is not sufficiently great, considering the distance, to prove anything." Prof. Barnard further remarks that although the Nova presented no nebulousity at its first appearance, it has always appeared as an undoubted planetary nebula since he observed it on August 19. Estimates of magnitude in the present condition of the Nova will depend greatly upon the telescope and magnifying power employed. Since August the nucleus has become fainter, while the light as a whole has remained essentially constant.

**"ASTRONOMICAL JOURNAL" PRIZES**—"A gentleman earnestly interested in the development and progress of astronomy in his native land has authorized the editor of the *Astronomical Journal* to offer two prizes, for resident citizens of the United States" (*Ast. Jour.* No. 284). The prizes will either take the form of money or of gold medals, one being of the value of two hundred dollars and the other of four hundred dollars. In the first instance the prizes will be awarded for observations tending to advance our knowledge of cometary orbits, one being for the best series of measurements of the positions of comets during the year ending March 31, 1894, and the other for the best discussion of the path of a periodic comet, with due regard to its perturbations. With regard to the first, astronomers who hope to gain the prize must frequently be at work until sunrise, as special value will be attached to observations made at inconvenient hours.

### GEOGRAPHICAL NOTES.

THE name Ibea, contracted from the initials of the Imperial British East African Company to designate their territory on the east coast of Africa, has acquired a certain amount of currency, and although open to philological criticism is practically convenient. On the same principle the great Dutch possessions in the East Indies have been termed *Ni* (*Nederlandsch Oost Indië*), and Mr. Ravenstein has suggested a similar abbreviation for the German East African territory (*Deutsch Ost Afrika*), only he would combine the initials with a Swahili affix or suffix signifying "land," and make it either *Udoa*, or *Doani*. The cumbrousness of using many words to specify a well-defined region seems to justify a somewhat bolder coinage of new names in geography than has hitherto been customary.

THE *Mouvement Géographique* publishes a sketch map of the Stanley Falls district of the Congo, compiled from the compass-bearings of M. Page, one of the members of the disastrous Hodder expedition. Besides Stanley, Lieutenant Gleerup and Dr. Oscar Lenz are the only other authorities on this stretch of the river. Special information is given regarding the three groups of rapids which occur between Stanley Falls

station and Kibonge. The cataract of Mandombe above Stanley Falls is composed of a succession of falls from six to ten feet high and numerous rapids, but local canoe-men are able to take boats through in four or five hours. Three hours of free navigation leads to the rapids of Mamanga, where the river is barred from bank to bank by a ridge of rock about twelve feet high, and followed by rapids and other smaller falls necessitating a portage. Three and a half hours of free navigation lead to Basundu, the last cataract, which canoes are able to pass in about three hours after being lightened.

THE Antarctic whaling fleet, the dispatch of which was noticed in vol. xlv. p. 477, has been reported from the Falkland Islands. The *Halcón*, which has the most complete scientific equipment, arrived at Port Stanley at the end of November, the *Active* on December 8, the *Diana* on December 11. The fourth vessel, the *Polar Star*, was spoken off the Plate on November 16. The telegram from Monte Video reports all well, and a preliminary notice of the scientific observations will probably follow by mail.

IN a communication to the Paris Geographical Society, M. Venukoff calls attention to the fact that although the extensive Government drainage works have almost obliterated the Pink marshes from the valley of the Pripet, the most recent non-Russian atlases continue to represent these marshes as they were thirty years ago. Now their site is largely forest and meadow-land.

### TRAVELS IN BORNEO

MR. CHARLES HOSE'S paper on "A Journey up the Baram River to Mount Dulit and the Highlands of Borneo," read to the Royal Geographical Society on Monday evening, was a pleasant variety in the succession of African papers which has formed the staple of the Society's programme for the session.

The Baram River runs on the whole northward through eastern Sarawak, reaching the sea in 4° 37' 15" N. and 115° 59' 30" E. Its mouth is complicated by a series of sandbanks shifting with the change of the monsoons. The river is in parts very deep, and is navigated by a fleet of Government steamers. The bordering land is low and swampy or covered with jungle until Claudetown, about sixty miles from the mouth, is reached. There the ground rises, and a prosperous trading town has been established by Chinese merchants. At Long Mari, about fifty miles further up, there are great rapids which can only be passed with difficulty, and gorges of considerable depth occur at intervals further up the stream. The journey to Mount Dulit was made up the Linjar, a large tributary of the Baram. The people on the banks of this river have a peculiar custom of keeping dead bodies in their houses encased in ornamental coffins for three months before burial, and Mr. Hose gave some highly interesting particulars regarding their burial customs, their complicated subdivisions of the world of the dead, and their habit of interchanging messages with departed friends. At the head of canoe navigation the Sibop tribe hunt various species of monkeys with the blowpipe, the valuable commodity being the intestinal calculi known as bezoar stones, which are greatly in demand by Chinese apothecaries.

The ascent of Mount Dulit was commenced on September 21, when a hut was built at the height of 2000 feet, and a path cut through the thorny scrub to 4000 feet, near which another hut was built. Several days were spent here collecting natural history specimens, many of which were species new to science, amongst the smaller quadrupeds *Hemigale hoesi*, and amongst birds *Calyptomena hoesi* and *Mesobucca eximius* may be mentioned. A cave some distance higher was found with wild tobacco growing at its mouth and several remarkable ferns, one with fronds 14 feet long; but except for bats and a solitary snake, the cave was untenanted. The fauna of Mount Dulit closely resembled that of Kina Balu, showing the widespread distribution in the highlands of Borneo of Himalayan forms. The flat moss-clad summit of Mount Dulit was found to be, by aneroid, 5090 feet, and there was a magnificent view of distant ranges, the position of a number of peaks in which was fixed. Some natives reported having heard a tiger roaring in the neighbourhood, but Mr. Hose found the sound to proceed from a gigantic toad, measuring 14½ inches round the body. At the close of the paper Dr. Bowdler Sharpe, F.R.S., pointed out the great importance of Mr. Hose's results in their bearing on geographical distribution.

## BACILLI IN BUTTER.

THE fact that milk affords a particularly suitable medium for the growth and multiplication of most micro organisms, has rightly led to its being regarded as a dangerous vehicle for the propagation of disease. On the Continent the practice of boiling all milk before use, and so destroying any pathogenic microbes which may be present, is almost universal, and recently a number of special pieces of apparatus have been devised for household use, ensuring the efficient so called "pasteurization" of milk. In England, however, we but rarely boil our milk in spite of outbreaks of diphtheria and typhoid fever having been not infrequently traced to a particular milk supply. In a paper by Cnopf on the bacterial contents of milk it is stated, that on one occasion out of every thirteen samples of milk supplied to Paris one was found to contain tubercle bacilli, whilst it is well known that the germs of typhoid, cholera, diphtheria, anthrax, &c., thrive readily in this medium. But although milk has been made the subject of much careful experimental investigation, comparatively little is known of the microbial condition of butter. Heim has shown that cholera bacilli purposely rubbed into butter could be demonstrated after thirty-two days, whilst typhoid bacilli similarly introduced were found after three weeks, and tubercle bacilli after the lapse of a month, although Gasperini discovered the latter in butter even after 120 days. Quite recently Lafar has published a paper, "Bacteriologische Studien über Butter" in the *Archiv für Hygiene*, in which he has recorded his investigations on the micro-organisms found in Munich butter. These experiments are instructive as exhibiting the fitness of butter to support a large number of bacteria, and thus furnish an interesting supplement to what is already known concerning the longevity of pathogenic microbes in this medium. The samples examined were prepared from fresh cream and were investigated as soon as possible after the butter was made. It was found that the number of microbes differed according as the portion for experiment was taken from the outside or from the interior of the piece of butter. Thus in one instance whilst one gram from the centre of the pat contained 2,465,555, on the outside in the same quantity as many as 47,250,000 micro-organisms were found. Taking the average of a number of examinations, it was estimated that the interior of a lump of butter possessed from 10 to 25 millions of bacteria in a single gram. Lafar is inclined to regard this as an under rather than an over statement of the number, inasmuch as there are always probably present a certain proportion of microbes which will not develop at the ordinary temperature, or on the gelatine-peptone medium usually employed. He graphically puts it that, in some cases it is conceivable that the number of organisms swallowed with a moderately sized slice of bread and butter may exceed that of the whole population of Europe! Lafar found that butter kept in a refrigerator, with a temperature of between 0° to +1° C at first (after five days) showed a marked reduction in the number of bacteria, but that no further diminution took place, although the sample was kept for a month at this temperature. Samples kept at from 12° to 15° C. exhibited a marked increase in the number of micro-organisms, a rise from 6 to 35 millions being observed in the course of nine days, whilst when placed in the incubator (35° C) after four days the bacteria had fallen from 25 to 10 millions, and after thirty-four days only 5 per cent. of the original number present were discoverable. Experiments were also made to ascertain what was the bacterial effect of adding salt to butter kept in a refrigerator. It was found that although the numbers were thereby considerably reduced, that yet, even when as much as 10 per cent. of salt was added, the complete destruction of the bacteria was not accomplished. On examining, however, gelatine-plates prepared from these samples, it was ascertained that the organisms present consisted almost entirely of a pure cultivation of one particular microbe, which was apparently entirely unaffected by the addition of salt, and had grown and multiplied to the exclusion of nearly all the other bacteria originally present. When samples similarly salted were placed in the incubator (35° C) the result was rather different, for whilst there was more apparent connection between the proportion of salt added and the diminution in the number of bacteria, more varieties of micro-organisms were found on the gelatine plates. But in this case, also, the germicidal effect produced was not proportional to the increase in the amount of salt. Samples of artificial butter were also examined, and were invariably found to be much poorer in bacteria than ordi-

nary butter. Thus, whilst the smallest number found in one gram was 747,059, in real butter considerably over two million microbes was the minimum. Two varieties of bacilli have been isolated and described, which were found very constantly present in butter throughout these investigations. They are beautifully illustrated and shown in coloured plates as individual organisms and colonies at the end of the paper. Lafar purposes continuing his investigations, and it is to be hoped that the examination of butter for pathogenic micro organisms, about which so little is known, will form an important feature in any further researches he may undertake.

GRACE C. FRANKLAND

## THE OCCURRENCE OF NATIVE ZIRCONIA (BADDELEYITE)

THE discovery of native zirconia was first made public in my letter to NATURE (vol. xlv. p. 620) in October last, at the same time I gave characters sufficient for the recognition of the new mineral, and suggested the name *Baddeleyite*, in honour of Mr. Joseph Baddeley who had brought the specimen with other dense minerals from Rakwana in Ceylon. As there was only a single fragment of what at first sight seemed a hopelessly imperfect crystal, the determination of all the important characters without appreciable injury of the specimen was a task of an attractive kind. The technical details of the investigation (including quantitative chemical analyses) and the line of argument by which definite results were evolved from the observations, were communicated to the Mineralogical Society at the meeting held on October 25 (NATURE, vol. xlv. p. 70), and crystals of hygroscopic zirconium oxychloride prepared by identical methods from Baddeleyite and artificial zirconia, respectively, were exhibited for comparison. Having regard to the unexpected result of the chemical examination and the difference of the characters of Baddeleyite from those of artificially prepared crystals of zirconia, every care had been taken to get results as accurate as the material itself would admit of.

Of course it was hoped that the occurrence of native zirconia, once established, would soon be noticed elsewhere, and in fact, I hear this morning (January 3) from Dr. Hussak of the Geological Survey of Brazil, that flawless crystals of zirconia are actually met with in the south of São Paulo as an accessory constituent of an augitic rock described under the name of Jacupirangite by my friend Mr. O. A. Derby.

The Brazilian mineral had three or four years ago been regarded by Dr. Hussak (who had then only a small amount of material for examination) as probably orthite (silicate of cerium, iron, &c.), a mineral with which it agrees in its more obvious external characters, and it was mentioned later under that name in Mr. Derby's description of the Jacupirangite, but more recently Dr. Hussak, on isolating a score of flawless crystals from the decomposed rock, recognized the distinctness of the mineral from orthite, determined the geometrical and physical characters of the crystals, and decided from a chemical examination that the material was a tantalo-niobate of probably some member of the yttrium cerium group. These results were published in the *Neues Jahrbuch für Mineralogie*, 1892, Band II, p. 142, immediately after my announcement of the occurrence of native zirconia in Ceylon had been sent for publication, but they had been forwarded from Brazil as early as the month of June. Dr. Hussak now informs me that the Brazilian mineral, which had been sent to Sweden for a complete quantitative examination, has been determined by Prof. Blomstrand to be almost pure zirconia.

As regards crystalline form, the parametrical elements obtained by myself for Baddeleyite, and announced at the meeting of October 25, agree in a very satisfactory way with those determined by Dr. Hussak for the Brazilian mineral, while as regards optical characters, the two descriptions are practically identical. The only important deviation of external character is in the specific gravity, that of Baddeleyite is 6.025, that of selected crystals of the Brazilian mineral is 5.006.

Now it seems almost impossible that the specific gravity of crystals of a simple oxide presenting otherwise identical characters can vary to this extent, and the explanation of all the difficulty will probably be found to be that Dr. Hussak's specimens really belong to two distinct minerals, that while the crystalline form and optical characters were determined from the one (zirconia), the specific gravity and the chemical composition

were originally determined from the other (yttrium tantalate). In fact, it was stated in my former communication that the Baddeleyite of Ceylon is itself associated with such a chemical compound, and I may add that this associated mineral was there designated without the mention of a species-name because it had been found to have a specific gravity (4.9) far below the inferior limit (5.5) hitherto observed in the case of undoubted Yttriotantalite. It was intended to determine later whether or not the lowness of the specific gravity was accompanied by a difference in the proportion of the chemical constituents, further, the similarity of aspect of the zirconia and yttrium tantalate of Ceylon is such that a confusion of the two would be easy. In this way the discrepancy of the chemical results and the complete accuracy of the observations of Dr Hussak, whose reputation stands so high in the annals of mineralogical science, would be found consistent with each other.

There remains the inconvenience that two names have been suggested for the same mineral, but according to the rules of nomenclature formulated by Dana (rule 13d) the name of *Baddeleyite* has the prior claim. I may add that the name *Brasilite* was in use eight years ago, commercially at least, for the specification of an oil bearing rock found in the neighbourhood of Bahia.

L. FLETCHER

### GAS POWER FOR ELECTRIC LIGHTING

At the ordinary meeting of the Institution of Civil Engineers on Tuesday, January 10, an interesting paper on "Gas-Power for Electric Lighting" was read by Mr J. Emerson Dowson. The author stated that in Great Britain alone gas-engines had been sold for electric lighting, exceeding in the aggregate 7000 horse-power, and that in Germany engines were used for about 1100 arc and 90,000 glow-lamps. It was, however, only within the last few years that gas-engines of large size had been before the world in a practical form. The varying load factor in central stations was a serious trouble, and the author hoped to show that much of the present loss, due to fuel, water, and wages, would be avoided if gas power were used instead of steam-power.

Special reference was made to the central-station at Dessau, belonging to the German Continental Gas Company. That station was opened in 1886 with two 60 horse-power, one 30 horse-power, and one 8 horse-power (effective) engines, worked with town-gas, and all the dynamos were driven by belt and counter-shafts. In 1891 considerable alterations were made. One 60 horse-power engine, with its belt and counter-shaft, was retained, and one of 120 horse-power introduced, coupled direct to its dynamo. The speed of the engine and coupled dynamo was 145 revolutions per minute, and the consumption of town-gas was equal to 39 cubic feet per kilowatt. Formerly, without accumulators, it was thought necessary to adjust the size of the engines to the supply, so that they should always be worked to their full extent. It had, however, been found that a limited supply could more advantageously be furnished entirely from accumulators. In spite of the loss of about 21 per cent in the accumulators, large engines worked more profitably in parallel than smaller ones supplying direct without accumulators. Since February, 1889, the Municipality of Schwabing, a suburb of Munich, had used an Otto engine worked with Dowson gas for 10 arc- and 300 glow-lamps. The load was variable, but with an average output of 22.5 kilowatts per hour the fuel-consumption was 3.3 lbs per kilowatt. The town of Morecambe was lighted by nine arc-lamps and glow-lamps, equal to 1600 of eight candle-power each, the dynamos being driven by Stockport gas-engines worked with Dowson gas. With an output of only 1155 kilowatts per week the consumption of fuel was 2.58 lbs, and the cost of the gas, including wages and fuel, was 3d. per kilowatt delivered. At the chateau of Mr. Say, at Longpont, in the South of France, there were 650 glow-lamps and one arc-lamp, supplied by a dynamo driven by a Cromley engine worked with Dowson gas. The consumption of fuel was 1.2 lb per indicated horse power, and 2.7 lbs per kilowatt per hour.

It was believed that the late Sir William Siemens first drew attention to the fact, that when illuminating-gas was burnt in a gas-engine to drive a dynamo, much more light was produced electrically than could be produced by burning the same quantity of gas in burners in the usual way. Latterly the consumption of gas per horse power in gas-engines had been reduced, and the

ratio was at the present time about 20 to 1 in favour of converting the gas into an arc-light, by means of a gas-engine. The author had collected data from various sources, as to the consumption of ordinary town-gas by engines supplying electric light with and without accumulators. The average of all the returns, with engines under varying loads and without accumulators, was about 47 cubic feet per kilowatt-hour; when accumulators were used, the consumption of gas was less, because the engines then worked under a full load. With 47 cubic feet per kilowatt, and 55 watts per 16 candle-power, one light of that power required only 2.6 cubic feet per hour, whereas a standard Argand burner required 5 cubic feet per hour. In this comparison, it was assumed that the glow lamps and gas-burners were in good order, but under ordinary working conditions they did not maintain so high a duty.

The question of load-factor was a serious one with any type of engine, but with gas-engines the loss was much less than with steam-engines. When a gas-engine was stopped, its consumption of fuel stopped also, and there was no furnace to maintain, nor was there any water to boil at starting. At the same time, it was desirable that the gas-engine should be worked as much as possible under a full load, and in this respect the experience at Dessau was generally confirmed. A central-station was worked under trying conditions, and in the London district there was only a full output of current during from three to five hours in every twenty-four; moreover, about 60 per cent of the total output was required during that short period. In practice, this meant that in a station where the current was supplied without accumulators, the engines were run at a reduced speed during a portion of the time, and at other times some of them were stopped altogether, but all had to be ready to work in the evening, and occasionally in the day time, when there was fog. Generally, it might be assumed that the average consumption was more than 6 pounds per kilowatt where accumulators were used, and about 9 to 12 pounds where they were not used. In any case, with the best possible arrangement of steam-power, there must be a large amount of fuel consumed which did no useful work, for, even if some of the fires were drawn, they had to be re-lighted, and the large quantity of water which had cooled during the time of standing must be re-heated.

The author believed that the solution of the difficulty was to be found in the use of gas-plant instead of steam-plant. With a large gas-engine, one brake horse-power per hour could be obtained with a consumption of about 1 lb of anthracite, or 1½ lb of coke, whereas the consumption of coal with the steam engines used for central-stations, must be taken at about 2½ lbs per brake horse-power, when working under a full load. A saving of not less than 50 per cent could therefore be effected in stations where the engines were fully loaded; and where there were great fluctuations in the output, the loss of fuel with boilers not used, or only partly used, could be almost entirely avoided. For a maximum of 400 kilowatts, there would be three gas-generators, each capable of supplying one-third of the maximum required. The production of gas could be raised or lowered in several ways, and the working of each generator could be stopped immediately by shutting off its steam supply. Supposing, therefore, that all three generators were working at their maximum rate, and a gradual reduction was required, this could easily be effected, and when the production of one or two generators could be dispensed with their operation was at once stopped. The third generator could then be kept at work, and its production adjusted to suit the minimum consumption required. A gas-generator had a small grate-area compared with that of a boiler, and much less cooling-surface. It contained no water, and required no chimney-draught. A generator of the size referred to lost only 6 to 8 lbs. per hour whilst standing. If an average of only 40 per cent. of the maximum power were required for twenty-one hours, it was equivalent to letting two of the generators stand for that period, and at 8 lbs each per hour that meant a total loss of only 3 cwts., compared with the much greater waste when steam-power was used. As the use of large engines, driven with generator gas, was of recent date, the author proceeded to describe the gas-plant used, and gave the results of engines working regularly with Dowson gas, under the usual conditions obtaining in factories. He also gave the results of brake-tests made with several engines of large size, and reproduced indicator diagrams taken from engines of different makers. Although admirable results had undoubtedly been obtained from engines

working with the Otto cycle, he was of opinion, that, with engines of large size, the results would be still better if the cycle were altered, especially when generator-gas was used. His reasons for this were fully stated in the paper.

The following was a summary of the points urged by the author.—

1.—When town-gas was used for driving the engines of an electrical station, the consumption was about 50 per cent less than the volume of gas required to give the same amount of light by ordinary burners.

2.—When town-gas was used, neither boiler nor firemen were required, and there were no ashes to remove; less space was needed, no accumulators were required, except such as might be necessary to equalize the load of the engines and to provide for a small amount of storage. The engines could be worked in the most crowded districts, close to where the lights were required, and where boilers were not allowed.

3.—When generator gas was used, the consumption of fuel under a full load would be at least 50 per cent less than with steam-power, and the loss due to steam boilers not being fully worked could be almost entirely avoided.

### UNIVERSITY AND EDUCATIONAL INTELLIGENCE

CAMBRIDGE.—We regret to hear that Professor Cayley has been suffering from serious illness, and that he is in consequence unable to give this term his advertised course of lectures in Pure Mathematics.

L. Cobbett, M.A., M.B., of Trinity College, has been appointed Demonstrator of Pathology in the place of Dr. E. Lloyd Jones, who has resigned the office.

Mr. F. Darwin, Deputy Professor of Botany, announces a special course of lectures in the Chemical Physiology of Plants, to be given by Mr. Acton, of St. John's College, on Tuesdays in the present Lent Term.

Mr. J. Y. Buchanan, F.R.S., announces a second course of lectures in Geography, to be given in the Easter Term.

Mr. A. E. Shipley has been appointed an additional member of the Special Board for Biology and Geology.

### SCIENTIFIC SERIALS.

*Journal of the Royal Agricultural Society of England*, 3rd series, vol. lli pt. 4.—Cottage sanitation (illustrated), by H. McLean Wilson, a paper prepared under the supervision of Dr. Spottiswoode Cameron and T. Pridgin Teale, F.R.S. It contains a discussion of the principal sanitary defects, which are most likely to be found in the houses of agricultural labourers, with valuable suggestions and remedies. The object aimed at is "to put the whole country, and every house in the country, into such a condition that if the epidemic (cholera) should break out it would have no chance of spreading."—Field experiments on the fixation of free nitrogen, by James Mason, gives an account of the enriching of some plots of poor land on the Oxford clay at Eynsham by the growth of two leguminous crops in succession. The two crops chosen were beans and mixed clovers. So far as they go the results are striking. Prior to 1888 the land had never been cultivated or received any manure. Brought into tillage in that year two plots produced 10½ cwts. and 9 cwts. per acre of barley and oats respectively, straw included,—an excessively low return. In the autumn of 1888 the plots were treated with 20 cwts. of basic slag per acre, and the subsoil with the same amount. Beans in the following year yielded an average of 46 bushels and 23 cwts. straw per acre. In 1890 mixed clovers gave a yield of 28 cwts. per acre as the average of the two plots, and in 1891 a crop of three tons clover-hay was obtained. Potatoes were grown upon the plots last year, and gave an average yield of eight tons per acre. Excepting the basic slag, no manure of any kind had ever been applied to the plots. The experiments are being continued and extended.—Wild birds, useful and injurious (illustrated), by C. F. Archibald.—Utilization of straw as food for stock, by Joseph Darby. Showing methods of using chaffed straw as a remedy for the deficient hay crop of last summer, with records of previous experiences under similar circumstances.—Yew poisoning, by Mr. E. P. Squarey, Mr. Charles Whitehead, Mr. W. Carruthers, F.R.S., and Dr. Munro. But few definite con-

clusions can be arrived at, owing to the conflicting nature of the information available. It appears, however, (1) that both the male and female yews are poisonous, (2) the poisonous alkaloid (or alkaloids) exists chiefly in the leaves and in the seeds, (3) the fleshy part of the fruit is harmless, or nearly so, (4) the amount of poisonous alkaloid in the leaves varies considerably with individual trees, and perhaps with the season of the year. Dr. Munro contributes a review of the chemical work done upon taxine, the only alkaloid in yew which has been investigated, very little is known with certainty about it, either as to its chemical nature or its physiological action. As Dr. Munro suggests, "yew leaves merit exhaustive chemical examination."—Besides the official reports, there are several short articles, including one upon the ferments of milk, abridged by Dr. Munro from Prof. H. W. Conn's pamphlet on the subject, issued last summer, also a paper upon the decline of wheat growing in England, by the editor.

*American Journal of Science*, January.—The age of the earth, by Clarence King. This paper contains an application of Lord Kelvin's reasoning from probable rates of refrigeration to the determination of the earth's age, aided by Dr. Carl Barus's recent work in geological physics, especially his determination of the latent heat of fusion, specific heats melted and solid, and the volume expansion between the melted and solid state, of the rock diabase. Thermal considerations have shown that with a given initial excess of temperature of the earth over surrounding space, and an assigned value for rock conductivity, it is possible to determine the curve of temperature from the earth's centre to its surface. It appears that for an initial temperature of 2000° C., the initial maximum temperature must still extend uniformly from the centre to within a few hundred miles of the surface for any admissible value of the age. But since the pressures increase steadily as we proceed towards the centre, there must be a point at which their effect outweighs that of the temperature, and the material, though very hot, remains in the solid state. Now on the data supplied by Barus's researches it is possible to state what temperatures are necessary to keep a certain representative species of rock in the fluid state at successive points within the earth. The amount of possible liquid layer is limited by the facts of tidal rigidity, which fix the maximum admissible temperature at 1950° and the age at  $24 \times 10^6$  years. Lower values are excluded by the gradient of temperature observed on proceeding downwards from the surface. This value, twenty-four million years, agrees fairly well with the age assigned by Helmholtz and Kelvin to the sun. It is also concluded that the earth never was all liquid, that the original liquid layer did not exceed 53 miles, and that the spheroidal shape is due to the plasticity of the lithosphere as manifested under the action of very slowly applied forces.—Tertiary geology of Calvert Cliffs, Maryland, by Gilbert D. Harris.—"Angleite" associated with boleite, by F. A. Genth.—Preliminary account of the lead bar base apparatus of the United States Coast and Geodetic Survey, by R. S. Woodward.—Some experiments with an artificial geyser, by J. C. Graham.—Observations of the Andromed meteor of November 23 and 27, 1892, by H. A. Newton.—Preliminary notice of a meteoric stone seen to fall at Bath, South Dakota, by A. E. Foote.—New Cretaceous bird allied to *Hesperornis*, by O. C. Marsh.—Skull and brain of *Claosaurus*, by O. C. Marsh.

*The Botanical Gazette* for October contains an interesting article by Mr. H. L. Russell on the bacterial investigation of the sea and its floor. The author has had the opportunity of carrying on bacteriological observations in sea water, both from the Bay of Naples and from the coast of Massachusetts. He finds micro-organisms invariably present in sea water, though not in such large numbers as in fresh water, even at a great distance from the shore, and to a depth of 3200 feet, and a larger number in the slime at the bottom than in the water itself. Some marine forms are cosmopolitan, and the bacteria that are so universally present in sea-water and mud seem to be quite peculiar to this habitat.—Mr. E. L. Berthoud describes the mode in which the geographical distribution of some plants has been greatly extended by the agency of the buffalo.—In the number for November Prof. Underwood gives a report of the proceedings of the International Botanical Congress lately held at Genoa.—Mr. G. W. Martin contributes an account of the development of the flower and embryo sac in *Solidago* and *Aster*.

*Bulletin of the New York Mathematical Society*, vol. II, No. 2, November 1892.—This number practically consists of one paper, and that a very interesting one, by Dr. Emory McClintock, "On the Non-Euclidian Geometry," a subject which has been more than once brought before our readers. In vol. viii (1873) appeared Clifford's translation of Riemann's Habilitationsschrift "Ueber die Hypothesen welche der Geometrie zu Grunde liegen" (1854). In 1883 this geometry was considered in Cayley's British Association address, and quite recently (February 25, 1892) in a translation of Poincaré's "Revue Générale des Sciences." "The chief lesson to be obtained from all non-euclidian diversions is that the distinguishing mark of euclidian geometry is fixity of distance-measurement, by which alone it is possible to draw the same figure upon different scales. That the same figure may be drawn upon different scales might well be laid down as the axiom necessary and sufficient to distinguish euclidian from non-euclidian geometry." To this is appended a footnote which says that this is "referred to as 'the axiom of similars' by Sir Richard (sic) Ball in the article 'Measurement' of the 'Encyclopædia Britannica'." A short article follows on the new logarithmic tables of J. de Mendizábal Iamborrel (Paris, Hermann, 1891). In addition there are the usual "Notes," but no list of publications.

No. 3, December 1892.—This number contains a careful criticism of Ball's "Mathematical Recreations," with suggestions and discussions by Prof. J. E. Oliver of Ithaca, New York, and an account of Dr. Julius Bauschinger's "Zweites Münchener Sternverzeichnis, enthaltend die mittleren Oerter von 18,200 Sternen für das Aequinoctium, 1880," by Prof. T. H. Safford. "Notes" and "New Publications" follow.

*Viedemann's Annalen der Physik und Chemie*, No. 12.—On the temperature coefficient of the electrical resistance of mercury and on the mercury resistances of the Imperial Institution, by D. Kreichgauer and W. Jaeger. The coefficient was measured in the case of the copies of standard resistances already described. The formula obtained for the resistance  $w_t$  at temperature  $t$  by two independent methods was

$$w_t = w_0 (1 + 0.000875t + 0.00000125t^2)$$

—Generation of electricity by friction of gases against metals, by K. Wesendonck.—On galvanic polarization at small electrodes, by F. Richarz.—Electric oscillations in wires, direct measurement of the moving wave, by Kr. Birkeland. The oscillations were produced in two copper wires running parallel to each other at a distance of 80 cm. They were 30 m long, and ended in one direction in brass plates 40 cm. square, facing two similar plates connected with the terminals of the spark gap of a powerful induction coil. The potentials along the wire when the coil was working were determined by measuring the length of the sparks crossing between the knobs of a spark micrometer, one of them being connected with the wire by a sliding contact, the other leading through a telephone to earth. Statical effects on the telephone were made inappreciable by laying a thread moistened with dilute sulphuric acid across the wires near the "collector" plates. Under these circumstances the passage of sparks was immediately indicated by the telephone, and their length could be measured down to 0.0005 mm.—Determination of dielectric constants by means of the differential inductor, by Oscar Werner.—Measurement of resistances by means of the telephone, by Max Wien.—Diffusion of light by rough surfaces, by Christian Wiener. Experiments made on cast gypsum show that Lambert's law of diffusion, according to which the brightness of a surface is independent of the angle from which it is seen, is not strictly correct. The brightness at the edge of a round surface is 0.6 times that given by his law. In the vicinity of reflection points the brightness is greater, and at the greatest brightness the angle of incidence is greater than the angle of reflection.—A unit for measuring intensity of sensation, by the same.—On internal friction of solid bodies, especially metals, by W. Voigt.—Measurement of the coefficient of diffusion of liquids, by F. Niemoeller.—Absolute compressibility of mercury, by G. de Meis.—Propagation of energy through the ether, by G. Helm.—On the utilization and action of the telephone in electrical null methods; reply to Hr. Winkelmann, by E. Cohn.—On the solution of sodium silicates, and influence of time upon their constitution, by F. Kohlrausch.—Behaviour of polarized light in refraction, by G. Quincke.—On a mercury arc light, by L. Aron.

## SOCIETIES AND ACADEMIES

LONDON

Royal Meteorological Society, December 21.—C. Theodore Williams, President, in the chair.—The following papers were read.—Moving anticyclones in the Southern Hemisphere, by Mr. H. C. Russell, F.R.S., Government Astronomer, New South Wales. The author describes the results of his practical study of the daily weather charts for Australasia, and states that the leading fact brought out is that the weather south of 20° S latitude is the product of a series of rapidly moving anticyclones, which follow one another with remarkable regularity, and are the great controlling force in determining local weather. These anticyclones are more numerous in summer than in winter, the average number for the year being 42. They usually take seven or eight days to travel across Australia in summer, and nine or ten days in winter, the average daily rate of translation being 400 miles. The shape of the anticyclone appears to undergo some modification as it nears the east coast. The winds on the north side of the anticyclone are not so strong as those on the south side, and the intensity of the weather is in proportion to the difference in pressure between the anticyclone and the V depression, but the relation of the pressures varies frequently before the wind responds, the pressure appearing to be controlled from above by the more or less rapid descent of air which feeds the anticyclone. Cyclonic storms are very unusual, and do not occur more than once in two or three months.—The tracks of ocean wind systems in transit over Australasia, by Capt. M. W. C. Hepworth. The author has examined the daily weather charts of Australia and New Zealand, and has prepared maps showing the daily positions of the centres of high and low pressures for a whole year. He finds that the wind systems, which make their first appearance to the westward and south-westward, advance to the eastward rapidly, and frequently very rapidly, during the winter months, but during the summer months they usually move more slowly, and not unfrequently recurve. Their progress is retarded by contact with the areas of high pressure which they encounter, the mean of the tracks of these anticyclones, moving also from west to east, appears to be across the southern portion of Australia and onward, crossing the islands of New Zealand during the winter months, but to the southward of Western and South Australia, across Victoria and New South Wales, and thence to the north-eastward, avoiding New Zealand during the summer months.—Rainfall of Nottinghamshire, 1861–90, by Mr. H. Mellish. The author has collected and discussed all the rainfall records made in the county during the thirty years, and finds that in the extreme west the mean rainfall is 27 inches or more, and that over the rest of the county it varies between 25 and 27 inches, except north of the Manchester, Sheffield and Lincolnshire Railway, where the rainfall is less than 25 inches, and in the north-east towards Gainsborough, where it is not more than 23 inches. The year of greatest rainfall was 1872, and of least rainfall 1887. October is the wettest month and February the driest.—A new instrument for cloud measurements, by Dr. Nils Ekholm.

Geological Society, December 21, 1892.—Prof. J. W. Judd, F.R.S., Vice President, in the chair.—The following communications were read.—On a Sauro-podous Dinosaurian vertebra from the Wealden of Hastings, by R. Lydekker. In addition to *Hoplosaurus armatus* and *Pelorosaurus conybeari*, there is evidence of another large sauro-podous Dinosaur in the Wealden, now known as *Morosaurus brevis*. Up to the present time it has been impossible adequately to compare *Hoplosaurus armatus* with *Morosaurus brevis*, but recently Mr. Rufford has sent to the British Museum an imperfect dorsal vertebra of a large Sauro-podous Dinosaur from the Wealden of Hastings, which enabled the required comparison to be made. The author describes the vertebra, contrasts it with that of *Hoplosaurus armatus*, and gives presumptive evidence that it should be referred to the so-called *Morosaurus Becklesii* (Marsh), which apparently cannot be separated from *M. (Cetiosaurus) brevis*. He has not been able to compare Mr. Rufford's specimen with the dorsals of the American *Morosaurus*, in order to discover whether the English Dinosaur is correctly referred to that genus. This paper led to a discussion, in which the chairman, Mr. Hulke, Prof. Seeley, Mr. E. T. Newton, and the author took part.—On some additional remains of *Ceratodus* and other fishes in the Green Gritty Marls, immediately overlying the Red Marls of the Upper Keuper in Warwickshire, by the Rev. P.

**B Brodie** The vertebrate remains occur in a very thin band of marly friable sandstone lying between two beds of green marl, though in some places the same bed has itself no admixture of sandy material. Bones and teeth are so numerous that it might almost be called a bone-bed. It does not exceed three inches in thickness. It contains Ichthyodolites of Cestracion fishes, abundant palatal teeth of *Acrodus kemperianus*, ganoid fish-scales, and abundant broken bones, some of which may belong to fishes, others to labyrinthodonts, and amongst the latter a fragment of a cranial bone. The Chairman congratulated the Society on the presence of one of its Fellows who had been connected with it for nearly sixty years, and had read his first paper almost half a century ago. He hoped that the Society would still continue to receive communications from the same source of like interest and value. Mr J W Davis, Mr H B Woodward, and Mr E T Newton also spoke. — *Calamostachys Binneyana*, Schimp, by Thomas Hick. Communicated by J. W. Davis. — Notes on some Pennsylvanian calamities, by W S Gresley. — Scandinavian Boulders at Cromer, by Herr Victor Madsen, of the Danish Geological Survey. Communicated by J W Hulke, F R S. During a visit to Cromer in 1891 the author devoted much attention to a search for Scandinavian boulders, and obtained three specimens, one (a violet felspar porphyry) was from the shore, and the other two were from the collection of Mr Savin. The first was considered to come from south east Norway, and indeed Mr K O Bjorlykke, to whom it was submitted, refers it to the environs of Christiania. The author considered that the two specimens presented to him by Mr Savin who had taken them out of Boulder Clay between Cromer and Overstrand, were from Dalecarlia, and these were submitted to Mr E Svedmark, who compared one of them (a brown felspar-hornblende porphyry) with the Grönklitt porphyry in the parish of Orsa, and declared that the other (a blackish felsite porphyry) might also be from Dalecarlia. This paper was discussed by Mr C Reid, Mr J W Davis, the Rev I B Brodie, Dr Hicks, Mr Marr, and the Chairman.

## EDINBURGH

**Royal Society, December 19, 1892.** — Sir Douglas MacLagan, President, in the chair. — Dr Hunter Stewart read a paper on an extension of Kjeldahl's method of organic analysis, and described an apparatus which he had devised for the estimation of the amount of organic carbon present in water. — Prof Rutherford read a note by Dr W G Aitchison Robertson on the madder-staining of dentine. Rabbits were fed on madder for some time and were then killed, the dentine being then found to be stained. When other food was supplied for a time, the process of feeding on madder being resumed afterwards, two coloured layers were found in the dentine, with an intermediate colourless layer. — Prof C G Knott read a paper on recent innovations in vector theory. He entered into a critical examination of the anti-quaternionic attitudes taken up by Prof Willard Gibbs, Mr Oliver Heaviside, Prof Macfarlane, and others. His chief arguments were (1) that the quaternion was as fundamental a geometric conception as either its scalar or its vector part—indeed more fundamental, (2) that in the development of his dyadic notation, Prof Gibbs, being forced to bring the quaternion in, logically condemned his own position, (3) that a really flexible vector analysis must be versorial, the equations  $i^2 = k, jk = i, ki = j$ , &c, being from the geometrical and physical point of view essentially rotational, (4) that the non-associative character of the vector-analysis, in which  $i^2, j^2, k^2$  were assumed to be  $+1$ , rendered it totally unfit for higher physical research, (5) that this tinkering with the algebraic sign quite spoiled the real efficiency of the very beautiful quaternion operator  $\nabla$ . — Prof Gibbs, for example, being compelled to introduce the (supposed) new functions of operation Pot, New, Lap, Max, which in quaternions are the very simplest of inverse functions of  $\nabla$ , and are best expressed as such.

## DUBLIN

**Royal Dublin Society, December 21, 1892.** — Prof A G Haddon in the chair. — Prof Sollas, F.R.S., read a paper on plicatone and andesite from tertiary dykes in Donegal. The author found that a microscopical examination of some remarkably fresh glassy rocks from Donegal revealed a close resemblance between them and rocks of the same age in Arran. This helps to confirm the supposed great extension of tertiary dykes through the north-west of Ireland. Prof Sollas next read a paper on the variolite and associated igneous rocks of Roundwood, co.

Wicklow. He described them as a complex of basic rocks, including altered ophioc dolerite, spilite (variolite du Drac), and spherulitic tachylite (variolite de la Durance). In connection with the epidiotisation of the rock the author pointed to the excessive fissuring which it has undergone, and showed that the formation of epidote is attended with considerable diminution of volume, sufficient to account for the cracks. The formation of serpentine and chlorite is attended with expansion, and chlorite can scarcely be formed without the simultaneous liberation of a disproportionately large percentage of quartz. This explains the common association of chlorite with the quartz of quartz veins. — Sir Howard Grubb, F.R.S., described a new system of mounting for monster reflecting telescopes. — Mr. H H Dixon read a paper on the germination of seedlings in the absence of bacteria. Seeds, the outer coats of which were sterilized, germinated in the absence of bacteria, and being kept absolutely free from bacteria did not, after growth had ceased, suffer the decay of death, but remained for more than twenty months apparently unchanged. An apparatus for sterilising the outer coats of the seeds and sowing them without the introduction of bacteria was also described. — A paper was communicated by Prof A C Haddon, and Miss A M Shackleton, describing some new species of Actinæ from Torres Straits.

## BERLIN

**Meteorological Society, December 6.** — Dr Vettin, President, in the chair. — Prof Assmann gave a detailed description of the meteorographs set up in the "Urania pillars." Each pillar contains a thermograph, a barograph, and a hygrograph, placed side by side in a metal case through which a rapid current of air is kept up. The thermograph consists of a Bourdon spring, filled with alcohol, whose movements are communicated to an external recording lever. The barograph is made of four boxes joined together, and delicately balanced by a weight, whose movements are similarly recorded externally. The hygrograph consists of a bundle of hairs 2 m in length. The above instruments have continued to work well after several months' use. Their chief defect is due to the hygroscopic properties of the paper on which the three levers trace their record. The large amount of material in the shape of meteorograms already collected has revealed a number of interesting facts. Thus, for instance, the temperatures recorded on two closely adjacent pillars may differ by 1° or more not only on a warm summer day, but also during the night of November 26, the coldest of this year. In one case the air was found to be warmed by the adjacent row of houses exposed to direct sunlight. In another the radiation was observed to be greater opposite a gateway than in the street. The very considerable local differences of air temperature recorded on closely neighbouring pillars could scarcely have been *a priori* expected.

**Physiological Society, December 9, 1892.** — Prof du Bois Reymond, President, in the chair. — Prof Exner, of Vienna, gave a résumé of his researches on the innervation of the crico-thyroid muscle in rabbits and dogs. In each he had found a branch from the pharyngeal branch of the vagus distributed to this muscle, together with the superior laryngeal nerve, to which he has given the name of median laryngeal nerve. The communication was illustrated by an experimental demonstration. — Dr Hansemann stated that he had obtained photographs of microscopic objects which when placed in a stereoscope, presented an appearance of solidity. They were produced by taking one photograph of the object in focus for a given level, and then a second photograph at a different level. These photographs united stereoscopically gave the impression of solidity. — Prof Hilgard drew attention to the remarkable fact that the most civilized races of antiquity usually established themselves in dry districts. This he attributed to the fact, borne out by numerous analyses of soils in America, that in dry regions the earth is far richer in mineral food stuffs necessary to plant life than in wet regions where these are largely washed out of the soil. Hence in dry regions simple irrigation suffices to produce a luxuriant vegetable growth, while on the other hand the soil of moist regions is very rapidly exhausted.

## PARIS

**Academy of Sciences, January 9.** — M de Lacaze Duthiers in the chair. — Drainage waters of cultivated lands, by M, I P Dehérain. An experimental investigation of the substances found in water drained from various cultivations showed that all the waters contained a fair proportion of nitrates. Even beet-root, which not only utilizes nitrogen for the formation of its

aluminoids, but also stores nitrates in its tissues, gave 31, 39, and 95 gr of nitric acid per cubic metre of drainage water. Beetroot gives, however, the least quantity of nitrogen in the drained water in proportion to the crop. Next comes Turkey corn, and then potatoes. It appears certain that all nitrogen which enters the soil is either assimilated or else lost. In the case of a bad harvest there is a loss both from the poverty of the crop and the impoverished state of the soil.—On the small planets and nebulae discovered at the Nice Observatory by MM. Charlois and Javelle, and at the Mounier observing station, by M. Perrotin. A list of eight minor planets discovered by the photographic method in four weeks, *i.e.* one-sixteenth of the time necessary to achieve the same result by eye observation.—Dilatation and compressibility of water, by E. H. Amagat. Tables are given showing the relative volumes of a quantity of water at pressures varying from 1 to 3000 atmospheres and temperatures ranging from 0° to 198°, and others showing the compressibility of water under the same conditions. This is seen to vary inversely as the pressure, and also inversely as the temperature up to very high pressures, when it begins to increase with the temperature.—Observations of Brooks's comet (November 19, 1892), made at the Paris Observatory (west equatorial), by M. O. Callandreaux.—Observations of solar phenomena, made at the observatory of the Roman College during the third quarter of 1892, by M. P. Tacchini.—On the reduction of elliptic integrals, by M. J. C. Kluyver.—On the thermal variation of the electric resistance of mercury, by M. Ch. Ed. Guillaume. Pointing out the remarkable agreement of his results with those obtained by Messrs. Kreichgauer and Jager, at the Physico-Technical Institute of Germany (see *Wiedemann's Annalen*, No. 12).—On the measurement of power in multiphase currents, by M. Blondel.—Absolute value of the magnetic elements on January 1, 1893. The elements for that date, determined at the magnetic observatory of the Parc Saint Maur, situated in long 0° 9' 23" E and lat 48° 48' 34" N, are the following—

	Absolute values on January 1, 1893	Secular variation in 1892
Declination	15 24.3	- 6.4
Inclination	65 8.5	- 0.5
Horizontal force	0.19596	+ 0.00016
Vertical force	0.42297	+ 0.00019
Total force	0.46616	+ 0.00024

The values for the magnetic and meteorological observatory of Perpignan, long 0° 32' 45" E, lat 42° 42' 8" N, are

	Absolute values on January 1, 1893	Secular variation in 1892
Declination	14 12.9	- 5.9
Inclination	60 13.3	- 1.8
Horizontal force	0.22278	+ 0.00030
Vertical force	0.38933	+ 0.00003
Total force	0.44856	+ 0.00017

—On the purification of arsenical zinc, by M. H. Lescoeur. Zinc destined for toxicological operations can be obtained free from arsenic, antimony, sulphur, and phosphorus by two successive operations, viz. oxidation by means of nitre, and fusion with chloride of zinc.—Combinations of quinoline with the halogen salts of silver, by M. Raoul Varet.—Symmetric dipropylurea and dipropylsulphurea, by M. F. Chancel.—On a substance derived from chloral, or chloralose, and its physiological and therapeutic effects, by MM. Hanriot and Ch. Richet.—On phagocytosis observed on the living animal, in the branchi of the lamellibranch molluscs, by M. de Bruyne.—New observations on the affinities of the different groups of gasteropoda, by M. E. L. Bouvier.—On an anomaly recently presented by the secular variation of the magnetic needle, by M. Léon Descroix.—Influence of motion on the development of fowls' eggs, by M. A. Marcacci.

#### AMSTERDAM.

Royal Academy of Sciences, December 24, 1892.—Prof. Van de Sande Bakhuyzen in the chair.—In a paper read by MM. S. Hoogewerff and W. A. van Dorp, some isomides of camphoric acid were described. These were obtained by the action of POCl<sub>3</sub> or CH<sub>3</sub>COCl on some substituted camphoric acids. The following reaction takes place—

where R is put for CH<sub>3</sub>, C<sub>2</sub>H<sub>5</sub> or C<sub>7</sub>H<sub>7</sub>. The isomides are very unstable, they easily add one molecule of water, re-generating the acids from which they derive. By the action of heat they are transformed into the ordinary imides C<sub>6</sub>H<sub>14</sub>-CO-NR.

—The same authors called attention to the fact that it seems to be a general reaction of the anhydrides of bibasic acids to dissolve in the aqueous solutions of ammonia and the primary amines, forming the corresponding acid amides: R-CO-NH<sub>2</sub> +

Mr. Bakhuis Roozeboom dealt with the solubility curve for systems of two bodies. The general form of such a curve in its totality, as yet not known even by the researches of Engel, has been encountered by the author and Mr. Schreinemakers in studying the solubility of Fe<sub>2</sub>Cl<sub>6</sub> 12H<sub>2</sub>O in solutions of HCl. The curve is a continuous one, combining the two solubilities of the hydrate, recently made known by the author. It presents a summit when the proportion of Fe<sub>2</sub>Cl<sub>6</sub> is the same as in the solid hydrate. Part of the solutions give on water-additions a deposit of the hydrate, part of them give redissolution. The general form of the curve for double salts would be represented in its totality by a closed curve, surrounding the point, indicating the composition of the double salt. With this form the same division of the solutions in regard to their behaviour on water-addition is possible as above.—Prof. Lorenz treated of Stokes's theory of the aberration of light. The hypothesis of M. Stokes, that the movement of the ether admits of a velocity-potential, is in contradiction with the supposition that, at the surface of the earth, the velocity of the ether is equal to that of the planet. It might, however, be doubted whether, in M. Stokes's explanation, the first hypothesis is really necessary. In the present note it is shown that it cannot be avoided.

## MODERN ADVANCED ANALYSIS

*Theory of Numbers* By G. B. Mathews, M.A. Part I  
(Cambridge: Deighton, Bell and Co., 1892)

THE book under review is a great contrast in many ways to the "Théorie des Nombres" of M. Edouard Lucas, the first volume of which has recently appeared under the ægis of Messrs Gauthier-Villars. The latter, reminding the reader much of the same author's "Récréations Mathématiques," exhales human interest from well-nigh every page. The former is on severe philosophical lines, and may be greeted as the first work of the kind in the English language. That this should be a fact is somewhat remarkable. When the late Prof. H. J. S. Smith died prematurely many years ago he left his fellow-countrymen a very valuable legacy. Fortunately he had been commissioned by the British Association to frame a report on the then present state of the Theory of Numbers, a subject with which he was pre-eminently familiar, and in which his own original researches had won for him a great and world-wide renown. The pages of the reports for the years 1864-66 inclusive yield as a consequence a delightful account of modern research in this recondite subject. It is, however, much more than a recital of victories achieved by many able men in many special fields. Prof. Smith's fertile genius enabled him to marshal the leading facts of the theory, and to impress upon them his own personality in a manner that was scarcely within the reach of any other man. He contrived to impart a glamour to those abstract depths of the subject to which few mathematicians have sufficient faith and energy to penetrate. Since that day the scientific world has been yearly expecting his collected papers. There is no doubt that their appearance will greatly stimulate interest and research in Higher Arithmetic. The reports of the British Association are not sufficiently accessible. Doubtless the papers will soon emerge from the hands of those upon whom has devolved the responsibility of their production. In the meantime we welcome Part I of the present work.

The theory of numbers is the oldest of the mathematical sciences, and may be regarded as their sire. Just as applied mathematics is based on pure, so pure mathematics rests on the theory of numbers. Every investigator finds that sooner or later his researches become a question of pure number. Continuous and discontinuous quantity are indissolubly allied. The theory of series, the theory of invariants, the theory of elliptic functions throw light upon and receive light from higher arithmetic. Algebra in its most general sense is everywhere pervaded by numbers. It may safely be affirmed that there is nothing more beautiful or fascinating in the wide range of mathematics than the interchange of theorem between arithmetic and algebra. A proposition in arithmetic is written out as a theorem in continuous quantity or conversely an algebraic identity is represented by a statement concerning discontinuous quantity. In this country the more recent advances in this attractive method are in large measure due to the labours of Sylvester and J. W. L. Glaisher. In a "Constructive Theory of Partitions,"

published some half-dozen years ago in the *American Journal of Mathematics*, Sylvester showed some beautiful progressions from arithmetic to algebra, and was followed in the same line by Franklin, Ely, and others, whilst in the pages of the *Quarterly Journal of Mathematics* and *Messenger of Mathematics* Glaisher has applied elliptic function formulas to arithmetical theory. The famous theorem which asserts that every number can be composed by four or fewer square numbers, was due to an application by H. J. S. Smith of elliptic functions to arithmetic. These interesting matters are not alluded to in this first volume.

Chapter I discusses the divisibility of numbers and the elementary theory of congruencies. Euler's function  $\phi(n)$ , which denotes the number of positive integers, unity included, which are prime to and not greater than  $n$ , is not treated as fully as might be desired. Gauss's theorem

$$\phi(d) + \phi(d') + \phi(d'') + \dots = n$$

where  $d, d', d'', \dots$  are all the divisions of  $n$  (unity and  $n$  included) is given, but not some interesting theorems connected with permutations, of which this is a particular case. Sylvester has written much about the same function, which he calls the "totient" of  $n$ . M. Ed. Lucas employs the term "indicateur" in the same sense, and believing that there is a great convenience in having a special name for the function, we regret that Mr. Mathews has not taken a course which would have familiarized students with Sylvester's nomenclature, and have enabled them to feel at home with much that has been written by him and others in this part of the theory of numbers.

The author states that this chapter is substantially a paraphrase of the first three sections of the "Disquisitiones Arithmeticae," the classical work of Gauss, we are inclined to think that advantage would have been gained if the paraphrase had not been quite so close. The next succeeding chapters are occupied with "Quadratic Congruencies" and the theory of "Binary Quadratic Forms."

The account given is fairly complete. There are so many proofs of Legendre's celebrated "Law of Quadratic Reciprocity" that it must have been difficult to make a selection. A wise choice has, we think, been made of Gauss's third proof as modified by Dirichlet and Eisenstein, the latter's geometrical contribution to the proof taken from the twenty-seventh volume of Crelle is, in particular, of great elegance. Gauss's first proof is also given, as well as references to several others. In the difficult subject of Binary Quadratic Forms, the author keeps well in view the close analogy with the algebraic theory of forms, so many additional restrictions present themselves that a large number of definitions are requisite at the outset, and this circumstance is apt to repel a student who approaches the theory for the first time. The definitions, in fact, constitute the alphabet of the science which must be mastered before progress can be expected in the appreciation of the wonderful beauties which are inherent in it. In this subject, more almost than in any other, the initial drudgery must not be shirked, and it may be said in favour of the present work that clearness of definition and conciseness of statement help the learner much to get quickly over the wearisome preliminaries.

We are glad to see the prominence given to the geometrical methods of Klein and Poincaré, that of the former is based on the theory of substitutions, reminding the reader much of the "Icosaeder", that of the latter is the "Method of Nets," a most ingenious geometrical application throwing light on the theory of "Reduced Forms."

The "Composition of Forms" given in Chapter VI is logically and judiciously developed, by means of the bilinear substitution, up to the point of showing the method of tabulating the primitive classes of regular and irregular determinants. The chapter on cyclotomy is one of the best written in the book. The discussion of the section of the periods of the roots of unity has engaged the attentions of mathematicians of the first rank since the time of Gauss, so that of necessity much has been written, and while the author states that he has given but an outline of an extensive theory which has not yet been completed, it may be said that the theory as given, with the references to authorities at the end of the chapter, will be quite sufficient to conduct the student bent upon research to the frontiers of the unknown country.

The determination of the number of properly primitive classes for a given determinant, applications of the theory of quadratic forms, and the distribution of primes complete the volume. Mr Mathews may be congratulated on his resolve to include Sylvester's masterly contraction of Tchébicheff's limits with reference to the distribution of primes, the reader is taken from the "sieve" of Eratosthenes to the work of Legendre, Meissel, Rogel, Riemann, and to the latest researches of Sylvester and Poincaré, of which the ink is scarcely dry. English mathematicians will turn with delight to the account given on page 302 of Riemann's great memoir of 1859, which contains the only satisfactory attempt to obtain an analytical formula for the number of primes not exceeding a given numerical quantity.

In conclusion, though the sequence of the subject matter may be open to criticism, we regard the book as a most valuable contribution to the small library of higher mathematical treatises that, owing chiefly to the energy and enthusiasm of the rising generation of mathematicians, is being brought together. How woefully deficient that library was but a few years since those engaged in research know only too well, and greatly do they rejoice as they see the yawning gaps one by one efficiently filled up. Part II of the task Mr Mathews has set himself to accomplish will, we hope, soon appear, and we trust he will be as successful with it as with the present Part I.

P A M

#### THE DARWINIAN THEORY.

*Darwin and After Darwin: an Examination of the Darwinian Theory and a Discussion of Post-Darwinian Questions.* By George John Romanes, M A, LL D, FRS. I. *The Darwinian Theory* (London: Longmans, 1892.)

WE had hoped ere now to have received the second instalment of this work, and to have dealt with the two volumes in a single critical notice. Unforeseen causes, one of them deeply to be regretted, have pre-

sumably prevented the appearance of the discussion of Post-Darwinian questions so early as had been anticipated. We therefore propose to give a short expository notice of the present volume, reserving such criticism as we have to offer for a future occasion, when the second volume shall have come to hand.

The first section consists of an exposition of the scientific evidences of evolution as a fact independent of the Darwinian theory of the method by which this evolution has been brought about. It may be regarded as an expansion of the author's little volume in the "Nature Series," on "The Scientific Evidences of Organic Evolution," published ten years ago. Mr Romanes has spared no pains in the collection and marshalling of his evidence. His object is to convince, by the abundance of facts and by logical inferences based thereon, those who still hold by the tenets of Special Creation. Whether those who still hold by these tenets are likely to be influenced by the facts or the inferences is a question we do not propose to discuss. The author evidently supposes that they are, and has written for them a good many pages in a strain of which we give a couple of examples.—"It would seem most capricious on the part of the Deity to have made the eyes of an innumerable number of fish on exactly the same ideal type, and then to have made the eye of the octopus so exactly like these other eyes, in superficial appearance, as to deceive so accomplished a naturalist as Mr Mivart, and yet to have taken scrupulous care that in no one ideal particular should the one type resemble the other." Again, "Although in nearly all the numerous species of snakes there are no vestiges of limbs, in the Python we find very tiny rudiments of hind limbs. Now, is it a worthy conception of Deity that, while neglecting to maintain his unity of ideal in the case of nearly all the numerous species of snakes, he should have added a tiny rudiment in the case of the Python—and even in that case should have maintained his ideal very inefficiently, inasmuch as only two limbs, instead of four, are represented?"

The second section of the volume is devoted to the setting forth of the theory of natural selection as it was held by the master. This, as was to be expected, is a well-ordered and lucid exposition. We could wish that Mr Romanes had been more careful to avoid all appearance of personifying natural selection. He says, for example, "It is the business of natural selection to secure the highest available degree of adaptation for the time being." Such language is highly metaphorical, if not misleading. If we can talk of business at all we may say that it is the business of various eliminating agencies, in the struggle for existence, to weed out and exclude from any share in perpetuating their race all those individuals who are too weakly to stand the stress of the struggle. The survival of the fit is an incidental result of the stern business of elimination. It is here that the naturalistic hypothesis differs most markedly from the teleological interpretation of nature. In conversation a while since a friend observed to us. Since your school of thought admit that the eye of natural selection is ever on the watch for the slightest improvement in adaptation, why should they hesitate to say with us that it is the eye of Beneficence that is thus ever watchful? The misunderstanding of the naturalistic position here

shown is not surprising. It is due to the too free use of metaphorical language on the part of expounders of the Darwinian hypothesis.

In the chapter entitled "Criticisms of the Theory of Natural Selection," an interesting digest is given of the work of Prof Ewart and others on the electric organ of the skate, concerning which Mr Romanes says, "I freely confess that the difficulty presented by this case appears to me of a magnitude and importance altogether unequalled by that of any other single case—or any series of cases—which have hitherto been encountered by the theory of natural selection." And he adds, "So that, if there were many other cases of the like kind to be met with in nature, I should myself at once allow that the theory of natural selection would have to be discarded," by which he means, we presume, that the theory would have to be discarded as offering a solution of such cases.

The book contains many excellent illustrations, the series which show the variations due to artificial selection being a noteworthy feature. They, and the volume which contains them, will prove of service to those general readers for whom, as the author tells us in his preface, this exposition of the Darwinian theory has been mainly prepared.

#### FERNS OF SOUTH AFRICA

*The Ferns of South Africa, containing Descriptions and Figures of the Ferns and Fern-allies of South Africa*  
By Thomas R. Sim. 275 pp., 159 plates. (Cape Town and Johannesburg J C Juta and Co. London Wm Wesley and Son, 1892.)

THE present work will be a useful and acceptable addition to our stock of fern books. It contains descriptions and plates of all the ferns and fern-allies known to exist in Africa south of the tropic of Capricorn, the same area which is included by Harvey and Sonder in their "Flora Capensis," three volumes of which, including the orders from Ranunculaceæ to Campanulaceæ, have been published. The author won the Jubilee gold medal given by the North of Scotland Horticultural Association, and for many years has filled the post of curator of the Botanic Gardens at King William's Town. Several years ago Mr Sim published an illustrated handbook of the ferns of Kaffraria, and now he has extended his area so as to include the whole of South Temperate Africa.

The fern flora of the Cape does not show the same richness and remarkable individuality which characterises its phanerogamic flora. It is probable that the flowering plants of this area are not less than ten thousand, and the number of large endemic genera and of species is very considerable. In ferns we get in South Africa 179 species, out of which 42 species, or something under 25 per cent., are endemic. There is no genus that is peculiar to the Cape, of Mohria, which comes nearest, the Cape species, *M. caffrorum* extends to Madagascar and Tropical Africa, and two new species have lately been found in the high regions north of the colony. The section Rhizoglossum of the genus Ophioglossum, which differs from the true adder's tongues by having the fertile spike separate from the barren frond, the single species, *O. bergianum*, is peculiar to the Cape.

Hymenophyllum is represented by 8 species, Trichomanes by 5, Adiantum by 6, Cheilanthes by 8, Pellaea by 14, Pteris by 7, Lomaria by 5, Asplenium by 25, Nephrodium by 12, Polypodium by 12, Acrostichum by 8, and Lycopodium by 8 species. Some of the species, e.g. *Vittaria lineata*, *Marattia* and the two tree-ferns, are tropical types, some, such as *Cystopteris fragilis* and *Lycopodium clavatum*, are common to Britain and the Cape. *Todea barbara* is confined to the Cape and Australia, and abundant in both areas. *Lomaria alpina* is a plant of all the three south-temperate areas. *Blechnum australe* of the Cape is not, I think, really distinct specifically from *B. hastatum*, and is widely spread in South Temperate America.

*Lomaria punctulata* is remarkable for its polymorphic fructification, which is sometimes like that of a Scolopendrium. *Asplenium lunulatum* is remarkable for its variability in outline and cutting.

Mr Sim gives introductory chapters on the parts of ferns and their nomenclature, on their reproduction and propagation, on their cultivation and the preparation of herbarium specimens, and on the history of the discovery of the Cape species and the books and papers that have been written about them. His statistic table on page 34 needs much revision in some of its items. He gives the ferns of Madagascar at 144. The number now known in the island is 326 true ferns and 40 fern allies, a total of 366. There are nothing like 683 species and 458 endemic types in Africa and its islands. When I counted them up in 1868 I made the two figures 346 and 127. Since that date probably 100 species have been added. Madagascar, Bourbon, and Mauritius are very rich in ferns, but Continental Africa is very poor both in number of species and in peculiar types as compared with Asia and America.

The descriptions are carefully drawn up from the study of actual specimens, and by the aid of these and the plates there can be no difficulty for any one, even without any previous botanical knowledge, in making out the name of any reasonably complete specimen of any of the Cape species.

Therefore, no doubt, the existence of such a book will give a great impulse to the study of ferns by ladies and others who reside in or visit the Colony.

J G BAKER

#### OUR BOOK SHELF

*Newcomb-Engelmann's Populare Astronomie, Zweite vermehrte Auflage*. Herausgegeben von Dr H C Vogel. (Leipzig. Wilhelm Engelmann, 1892.)

THE well known Popular Astronomy of Prof Newcomb was translated into German by Rudolf Engelmann, and published in 1881 with considerable additions and alterations, most of which were improvements. It was very favourably received on its first appearance in German, probably because it is not only comprehensive, exact, and scientific, but has a fresh and vigorous style, in pleasing contrast to the ponderous German standard works. The original translator being dead, the publishers entrusted the work of preparing a new edition to Dr H C Vogel, Director of the Astrophysical Observatory at Potsdam, a task for which he was specially fitted, because astronomical progress during the decade since the appearance of the first edition of the book has been mainly in his special

department. Dr Vogel's chief difficulty has been to keep the book within reasonable limits while bringing it up to date, but he has not been wholly successful in this. By a slight further enlargement of the book he might without difficulty have very much increased its value. A description of the diffraction spectroscopy should have been given in the section on spectroscopes, Prof Hale's work in photographing prominences and faculæ should have been introduced; the chapter on Mars is very much behind the times, and some details should certainly have been given of the international scheme for photographically charting the stars.

Dr Vogel has considerably altered the arrangement of the chapter on comets and meteors, and this alteration has led to the curious result that the same woodcut appears as Figs 152 and 165. The chapter on stellar astronomy is also recast, the editor's own latest classification of star spectra being given to the exclusion of all others. The section on variable stars has also been entirely rewritten. These chapters would have been much improved by an account of recent discoveries as to the resemblances between comets, nebulae, and stars, and of the theory that variable stars are formed of revolving swarms of meteorites. The classification of star spectra which recognises an ascending and descending temperature should have been given, and recent work and theories on temporary stars certainly deserved attention. The bibliography given in the first edition has been omitted in the second, as being too much for the general reader, and insufficient for the student of science. The excellent series of biographical notices in the appendix has been carefully extended to 1891, and completely rearranged. Dr Vogel has adopted the admirable plan of arranging these notices chronologically in order of death, instead of birth, probably on the grounds that all work is largely the result of previous discoveries, and that the later years of a man's life are usually his best and most productive. A series of excellent tables and a full index complete the volume.

The general appearance of the book has been much improved by the use of new woodcuts for the illustrations, and by the substitution of two excellent photographs of nebulae (those of Orion and Andromeda) for the very unsatisfactory star charts of the earlier edition.

A T

*The Hemiptera Heteroptera of the British Islands* By Edward Saunders, F.L.S. (London, L. Reeve and Co, 1892)

It is now nearly thirty years since Douglas and Scott first made the study of the British Hemiptera Heteroptera possible to ordinary students by the publication of a description of these insects in a volume issued by the Ray Society. The difficulties were then very great, for purely insular ideas in entomology were prevalent, and our hemipterous insects had not been sufficiently compared with continental species. Douglas and Scott did all that was possible at that time and produced a good work that has held the ground as the best published authority on the subject. Very much, however, has been done since that period, and restricted specialists in entomology, as in most other branches of natural science, have exercised unlimited time and patience in studying the classificatory problems of a single family or even of a large genus. Hence in a monograph of to-day the standard of advanced classification and descriptive facility is considerably raised from that which dominated the writings of the earlier authors. Mr. Saunders has not only aimed at this perfection, but has sought to place in the hands of the British student and collector a thoroughly trustworthy handbook by which he may understand and identify his collection, and in this we think the author has altogether succeeded. We must not look for bibliographical references or synonymical notes, the

names of the describers of families, genera, and species being only indicated, while the habitats of the species are confined to such localities in the British Islands as are recorded by collectors, and this is perhaps all that can be expected in a local monograph. It is therefore in no spirit of criticism we express a regret that in all faunistic writings the complete recorded distribution of the species is not given. Thus even the purely British collector would not be the worse for learning that *Zicrona cerulea*, to be found in the suburbs of London, is not only widely distributed throughout the Palaearctic region, but is also found in Continental India and in the Malay Peninsula and Archipelago; or that *Ischnorhynchus reseda*, to be taken even at Hampstead, is common throughout Europe and Siberia, and is also neither scarce in North nor in Central America.

We welcome Mr Saunders's book as a distinct and valuable addition to our insular entomological literature. We also notice that an illustrated edition is advertised, but on the quality of the plates we are compelled to be silent, as the publishers have only forwarded us a plain copy. W. L. D.

*Physical Education* By Frederick Treves, F.R.C.S. (London, J. and A. Churchill, 1892.)

THIS essay is reprinted from the "Treatise on Hygiene" by various authors, edited by Stevenson and Murphy, the first volume of which we recently reviewed (NATURE, vol. xlii p. 609). It well deserves to be issued separately, for the author has mastered his subject thoroughly, and sets forth his ideas in a plain, straightforward style which will be cordially appreciated by readers who are especially interested in athletics. Mr Treves is quite as strongly conscious of the evils which may spring from excessive or unsuitable physical exercise as of those which may result from physical exercise being neglected or underrated, so that there is a welcome tone of perfect impartiality in all he has to say about the various ways in which efforts are made to promote health by the use of the muscles. The volume may be confidently recommended to all who desire to understand the conditions under which physical exercise is most likely to be of service.

## LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

### The Geology of the North-west Highlands.

IN the kindly review of my work by Prof de Lapparent, which appeared in NATURE of 5th inst, there are one or two inaccuracies which I would at once have corrected had I not shrunk from drawing attention, even for purposes of rectification, to an article which I felt to be too eulogistic. Lest, however, my silence be misinterpreted, there is one point on which I wish to say a few words. Prof de Lapparent, when alluding to the solution of the problem of the geological structure of the North-west Highlands, makes no reference to the distinguished part taken in that subject by Prof Lapworth. But every one who has followed the progress of geology in recent years is familiar with his work. For myself, I have had no personal share in the discovery. Like most geologists I had accepted the views of Sir Roderick Murchison, and I held to them, until, after the Geological Survey was for the first time extended to Sutherland in 1883-84, I was finally convinced that they were untenable by the brilliant mapping of my colleagues, Messrs Peach and Horne, who, following Prof Lapworth's lead, share with him in the glory of one of the greatest achievements of field geology in recent times. My recantation was published in NATURE of November 13, 1884, and the whole history of the investigation of the North-west Highlands up to Prof. Lapworth's latest paper

was sketched in a detailed Report communicated by me to the Geological Society on April 25, 1888. My friend Prof Lapworth has no scientific comrade who has more frankly and practically acknowledged his great geological achievements than I have done.

ARCH GEIKIE.

January 23, 1893

### The Identity of Energy

I AM glad to see that in the introduction to his severely-difficult memoir, published in the *Philosophical Transactions* for 1892, "On the Forces, Stresses, and Fluxes of Energy in the Electromagnetic Field" (p. 427), Mr. Oliver Heaviside notices and criticizes some ideas of mine, published in the *Philosophical Magazine* for June 1885 and other places, concerning energy.

The statements I then made, and to which I still rigidly hold, are (1) that energy has identity like matter, and not merely conservation, (2) that whenever energy is transferred from one body to another, it is also transformed from potential to kinetic, or *vice versa*.

The basis of the first assertion is the fact that energy is always passed on continuously through space, i.e. that its transfer occurs along a definite path, instead of merely appearing in one place and disappearing in another.

The law of conservation would be satisfied by disappearance and equal reappearance, the law of identity requires a continuous act of transfer. The latter is true for matter, and I assert that by thinking of a number of instances, it will be perceived true for energy. In all mechanical instances, as of belts and shafting, the transfer of energy is obvious, it was not so obvious in electromagnetic actions, between dynamo and motor for instance, until Prof. Poynting clearly demonstrated that it was in accordance with Maxwell's principles.

Mr. Heaviside objects that we are not able to assert it for gravitational energy. Well, that depends on what view we take of gravitation, but I submit that until something more is certainly known about it, the safest plan is not to assert, but to assume, that in this case also what is known in every other case likewise occurs, and to trace the consequences of the hypothesis in the hope that it may lead to some conclusion verifiable or falsifiable by experiment. The reason I attach importance to this doctrine of the identity or continuity of transfer of energy is because it greatly simplifies the fundamental mechanical laws, and emphasizes without risk of vagueness the denial of action at a distance.

If action at a distance (no matter how minute) can ever occur, then indeed the continuous transfer of energy breaks down. But observe that there is no necessity for the transfer to occur at a finite velocity in order to avoid action at a distance, i.e. action without a medium. By the thrust of an incompressible pole, energy is transferred from butt to tip just as really as if the compressed and recoiling layers could be demonstrated and its velocity measured. So likewise the pull of gravitation may be (and *pro tem* I believe is) transmitted by an incompressible (or nearly incompressible) ether, so that the force is felt instantaneously (or nearly instantaneously) at all distances where matter exists, but that by no means militates against a genuine act of transfer. The conservation of matter makes experiments on gravitation difficult; if we could suddenly create or destroy a piece of matter there might be some remote chance of determining the rate at which its gravitative influence was felt. Especially if by alternately generating and destroying it we could set up a series of waves of perhaps measurable length.

And although this is as yet impossible, many known facts lead us to conclude that if gravitation has any velocity at all short of infinite, it is at least immensely greater than the speed of light. And seeing that the one phenomenon is concerned with the transverse (electric) elasticity of ether, and the other with its longitudinal elasticity, there is nothing surprising in that.

By all means, however, as Mr. Heaviside urges, let gravitation be included in general etherial equations whenever possible; and it may perhaps be wise to assume some unknown finite rate of propagation and trace its consequences with the object of verifying or disproving them.

So far as I understand, however, this is not unlike what Helmholtz did, by his generalization of Maxwell's electromagnetic theory; with the result that the course of experiment so far has been to justify the simple Maxwellian theory, and to make the longitudinal ether thrust velocity practically infinite.

And now for the second assertion, that whenever energy is transferred from one body to another, it is also transformed, and *vice versa*. This is to me not an opinion, but a demonstrated theorem (as has been shown in the paper referred to), but it must be understood in what sense I consistently use the word body in this connection. I do not necessarily mean a visible lump of matter. The molecules of a lump are to be regarded as a different "body" to the whole mass, and again, the ether everywhere emulating them is another distinct "body."

But so long as a piece of matter is merely moving through space with all the energy it may happen to contain, I do not consider that a transfer at all. There is a transfer of energy in one sense, viz. that of locomotion, but there is no transfer from one body to another except when work is done at their point of contact, and energy gained by one and lost by the other, being transferred across their common boundary surface. In all such cases of "activity" the energy transferred is necessarily in the first instance transformed, though by means of another transfer it may very speedily be transformed back again, and so speedily sometimes is the re-transformation effected that the intermediate condition has a tendency to get overlooked. In wave-motion a transfer and transformation occurs during every quarter period.

Mr. Heaviside seems to think that the mere convection of energy should be included as one kind of transfer, but surely that is scarcely convenient? So long as energy retains its form and adherence to one body, so long there is no true activity, no work is being done—the energy is simply stored. It may be stored in a bent spring, or in a flying bullet, or in a revolving fly wheel. It is impossible to have kinetic energy at all without convection, and a distinction must be drawn between the mere existence of energy and the active and useful flux or transfer of the same.

Mr. Heaviside further seems to consider circulatory fluxes of energy as strange and useless phenomena. But I see no reason in this at all. The circulation of matter—for instance in the inner circle of the Metropolitan railway—is, I suppose, considered useful. The circulation of commodities is the essence of commerce. So does the circulation of energy constitute the activity of the material universe. It is the act of transfer that is beneficial (or the reverse), what becomes of a conservative quantity is a minor matter. It must go somewhere, and may very well, after a series of transfers, ultimately return to its starting point. [Parenthetically I should like to preach here against what I hold to be the pernicious doctrine of (at least amateur) political economists, that because money locally spent is not destroyed, but remains in the community, it does not much matter how much transferring power is permitted or granted to one individual,—as if the money itself were the useful commodity, and not the power of determining its direction of transfer or non-transfer. The control of every transfer should be jealously watched, for that is the greedily-desired power.]

So long as circulatory convection of energy goes on *without* transfer—as, for instance, in the rim of a non-working fly-wheel—so long the energy is merely stored, but directly a belt is fitted on with different tensions in its two halves, a portion of the energy is tangentially tapped off, and transfer and activity begin. The kinetic energy of the wheel is converted into strain or stress energy of the belt, which then by simple locomotion passes it on to something else. I perceive, however, that there is a slight difficulty about this simple case of locomotive conveyance of stress energy by a really inelastic substance; but only because the details of any infinitely rapid process are difficult to follow. I perceive moreover that in many cases it is not worth while to attend to the alternate compressions and motions which constitute a longitudinal pulse, and that the idea of simple locomotion may be conveniently introduced to cover the case of a stressed body moving; but the convenience is I think only attained by shutting our eyes to the essential processes which in all actual matter must be occurring.

I trust that Mr. Heaviside may find time to notice this letter, and attack anything he disagrees with, in order that the whole matter may become thoroughly clear.

OLIVER LODGE

### A Proposed Handbook of the British Marine Fauna

I AM obliged to Prof. Thompson for his criticism of my scheme, although only one of the points he raises is new to me—as I think it will be to most zoologists—viz. that "there are no nematophores on the stem" in *Antennularia*. I thought A

*ramosa* had nematophores on the stem, and I think so still. Some of his other remarks are so very obvious as to have scarcely required mention, at any rate to biological readers, a few, however, are just such debateable points as I was anxious to have opinions upon from as many naturalists as possible, and I am glad to know Prof. Thompson's. I am glad to say a number of biologists have written to me, since the scheme appeared in NATURE, expressing general approval, and criticising various points of detail, and some of them kindly making offers of assistance in special groups—and without that kind of assistance from specialists I need scarcely say it would be impossible to carry out the work satisfactorily. The proposal was first brought before the Biological Society of Liverpool on November 11, and it was only after some weeks of intermittent discussion with some of my friends in that Society (such as Dr. Hanitsch, Mr. Isaac Thompson, and Mr. A. O. Walker) who are specialists in certain groups of marine invertebrates, and after correspondence with Canon Norman and other biologists, that I sent the scheme to NATURE, with the view of getting further opinions. Consequently some of the debateable matters alluded to by Prof. Thompson (limits of British area, introduction of certain non-British forms, specific nomenclature, how to treat records of size and distribution, best terms to use for zones of depth, and, I may add, for relative abundance) have already been considerably discussed. The other points raised by Prof. Thompson in connection with *Antennularia* only require a few words. I said *A. ramosa* was usually branched. Prof. Thompson says it "may sometimes" be unbranched. The difference between these statements is slight. As to dimensions, a zoophyte which grows to 12, or occasionally to 24, inches in height, will, of course, be also frequently found of smaller sizes, and it might be the best plan to give the extreme range, say, 1 to 24 inches. What I gave was the fair average size of most of the specimens dredged or seen in collections, which I still consider to be 6 to 9 inches.

The rest of Prof. Thompson's contention is practically that there are great difficulties in the way of drawing up such a book of the known British marine invertebrate animals, and that if it is ever done it will be more or less incomplete, because Canon Norman and others (I hope including both Prof. Thompson and myself) will continue to find new British animals. That is perfectly true—in fact obvious—but the same objection applies more or less to every work on systematic zoology that has ever been published, and I do not consider that because our British Pycnogonids, and some other small groups, are still very imperfectly known, that is any sufficient reason for delaying indefinitely an attempt to deal with the rest of the invertebrata. On the contrary my opinion is rather that an approximation is better than nothing, and that every group, or every family, reduced to "Handbook" form with specific diagnoses and figures must be a distinct gain. I hope Prof. Thompson will not think that I am trying to dispute all his criticisms, or that I am ungrateful for the trouble he has taken. I have no doubt that he could correct me in many details, and give me great assistance in records, &c., of zoophytes, pycnogonids, and other groups, and I hope he will do so. W. A. HERDMAN

University College, Liverpool, January 20.

PROF. D'ARCY THOMPSON'S letter raises a question which is, I think, well worthy of Prof. Herdman's consideration. That a handbook of our marine fauna is needed cannot for a moment be doubted, and the only matter that calls for discussion is one of scope and method, of ways and means. Prior to the appearance of Prof. Herdman's circular and article I had intended, if possible, to bring this very matter before the British Association at its next meeting, believing that a select Committee of the Association would best be able to further the interests of marine zoology in this respect. But, as the matter now stands, I leave any such action very willingly to Prof. Herdman's initiative.

Put broadly (although I well know that such a work in Prof. Herdman's hands would by no means have the character of a mere compilation), the question at issue is whether the handbook should be mainly a compilation from existing material, or should express the work of various specialists and be based upon a series of special investigations. For myself I agree with Prof. Thompson, and for the same reasons, that the adoption of the latter alternative would be likely to meet our needs most fully and satisfactorily. It would ensure, as far as possible, the equal treatment of the various groups, and would thus give to

the book (which is important) a more permanent and authoritative value than could be attained by a book depending upon the personal labours of one zoologist. I feel confident that, should Prof. Herdman admit the force of this consideration and be willing to edit a handbook in which the diagnoses were drawn up for the various groups by specialists or specially chosen investigators, he would find no difficulty whatever in meeting with willing co-operation.

But I hardly see the point of extending the scope of the work to the extent which Prof. Thompson would seem to desire. We need a handbook for use around the coasts of our own islands. To include the fauna of the whole North Atlantic would needlessly add to the size of the work, delay the time of its appearance, and even in the end be incomplete, while it is doubtful whether the advantages would at all outweigh these defects.

W. GARSTANG

Marine Biological Association, Plymouth, January 20

#### Fossil Plants as Tests of Climate

MR. J. STARKIE GARDNER, in his interesting review of Mr. Seward's valuable essay, makes a statement which I fancy may be misinterpreted at page 268 of NATURE, where he speaks of the fragmentary character of the Arctic tertiary plants, and the inexperience of the collectors. He doubtless is referring to the remains of certain supposed "palms and cycads in the Greenland Eocene," but those who have not followed this branch of Arctic research would hardly gather from the review that Prof. Heer has determined a magnificent flora of more than 350 species from these northern tertiaries, and that he at once pointed out the absence of tropical and subtropical forms, and the fact that large leaves are not only perfectly preserved up to their edges, but that upright trees associated with their fruits and seed prove them to have grown on the spot. "Thus of *Sequoia Langsdorffii*," he writes, "we see not only the twigs covered with leaves, but also cones and seeds, and even a male catkin."

In April 1875 I endeavoured to give an abstract of all that was then known of Arctic geology, in a series of articles that appeared in your columns (NATURE, vol. xi pp. 447, 467, 492, and 508), and added some general conclusions of my own, which are further accentuated in the joint communications of Colonel Feilden and myself to the Geological Society in 1878, and in the "Geology Appendix" to Sir George Nares' "Voyage to the Polar Sea," in which expedition Colonel Feilden played a most valuable part. I have ever since carefully followed the progress of Arctic research, and am now of opinion that looking to the identity of a large number of species (often extending to the varieties of the same) occurring in the Silurian, Carboniferous, Lias, Oolite, Cretaceous, and Tertiary strata of the Arctic regions, with those occurring in similar strata in Europe and other parts of the world, they point to a common temperature over these areas and probably over the whole world, from Silurian to early Cretaceous times, and that this was the case does not appear to me to be affected by the question as to whether or not these deposits were homogeneous.

In late Cretaceous times commenced horizontal variation of cold, or what we now term "climate," though previously vertical variation had evidently been present, for the later investigations of Messrs. Blanford appear to place beyond doubt the existence of glaciers in geological times, as was suggested in 1855 by my lamented chief, Sir Andrew Ramsay, but I equally fail to see that the slightest evidence has been anywhere adduced to support the theory of "recurrence of ice-ages," originated by my talented colleague the late Dr. Croll, and now supported with a "modification" by Sir Robert Ball.

The facts, whether we look to the history of plant life, or animal life, or the character of the rocks themselves, appear to me to be all the other way, as they disclose nothing resembling the refrigeration that, gradually increasing in the Tertiary epoch, culminated in the Glacial episode, which choked up the North and Irish Seas with an ice-sheet since man has been an occupant of our islands.

CHAS. E. DE RANCE.

H. M. Geological Survey, Alderley Edge, Manchester.

#### Racial Dwarfs in the Pyrenees.

IN consequence of evidence that I had obtained as to the existence of a dwarf race in Spain, I wrote to Mr. McPherson,

"On the Miocene Flora of North Greenland," by Prof. Oswald Heer. Translated by R. H. Scott, F.R.S., Brit. Assoc., 1867, pp. 52.

our Consul at Barcelona, and enclose his reply. There have long been rumours of survivals of a dwarf or a prehistoric race existing in parts of Spain, but careful inquiries at Madrid failed to supply any definite information on the subject. Last summer on reading over an old number of *Kosmos* (Paris, 1887), I found a brief paragraph referring to a pigmy race having been found in the province of Gerona, Spain, who had slightly Mongolian eyes, yellow, broad, square faces, height from 1 m 10 to 1 m 15, and red hair.

An Austrian gentleman recently told me he had seen, in the market-place at Salamanca, some very under sized peasants, with broad faces and mahogany-coloured woolly hair.

You will see that these accounts all agree substantially, and that these dwarfs and those of Africa are precisely similar.

I have got a deal of information from an old Spanish woman who belongs to a half breed nano family, and who says that there are in such families frequently nanos (or "enanos") who have red tufts of wool, and are as small as ordinary small boys. But these tufts of wool are peculiarly characteristic of dwarf races nearly everywhere.

I shall write more fully as to my inquiries among half breed nanos, but they are of very secondary interest now that we can find pure racial nanos within easy reach.

It is most fortunate that they live in the Valley of Ribas and the Col de Tosas, within a little more than a half-day's journey from Toulouse. Some health-seekers or tourists in the South of France may perhaps feel inclined to pay a visit to these little people.

Should the suggestion be acted on, and prove satisfactory, a line to myself on the subject, addressed to 28, Pall Mall, would be highly valued.

R G HALIBURTON

Tangier, January 9

[COPY]

"British Consulate, Barcelona, December 10, 1892

"DEAR SIR,—Since I received your letter of November 18 and its enclosures I have endeavoured to ascertain what truth there is in the statement that pigmies, or 'enanos' (not 'nanos') exist in the Valley of Ribas. From conversations I had with various individuals who have visited that district it appears certain that a race of men, of about from one metre to one metre and twenty centimetres high, of a darkish complexion (copper-coloured), dark hair and woolly, and flat, broad nose, live in that district, particularly in the 'Collado de Tosas.' They are active, and are generally employed as shepherd. It is also asserted that they are not very intelligent, and that they appear to understand and to make themselves understood with difficulty. It would be an easy journey to go to that place from this town. I had no little difficulty in finding out that such a race lived in that place, for many of the persons with whom I have spoken on the subject were evidently confused and confused me, as besides these, evidently racial pigmies, there are in that neighbourhood many 'cretins,' which were at times described to me as if these were the 'enanos.' I spoke about I am now certain that there are cretins and pigmies in the Valley of Ribas. It is stated that the 'enanos' are rapidly disappearing, and that latterly many have died of smallpox. The men you speak of, who were seen at Salamanca, are, I should say, natives of the Batuecas, or rather of Los Hurdes. These men were discovered in the sixteenth century, and they were then and are even now, in an almost absolute state of savagery." [The remainder as to this race is omitted, as it does not appear that they are nanos.—R G H.]

"Yours very truly,

(Signed)

"WM McPHERSON.

"R G Haliburton, Esq."

#### British Earthworms

I WRITE to suggest—in connection with the recent letters in *NATURE* upon this subject—that some one give a thoroughly trustworthy list of British earthworms, with the memoirs in which the species were originally described, and the chief characteristics of each. Dr. Benham would be doing very useful and acceptable work if he were to accomplish this. From what I understand everybody has been making mistakes, and the whole matter is in the utmost confusion. It is very necessary that

NO. 1213, VOL. 47]

such a classification should exist, if only for the benefit of those who are working on the earthworm more from a comparative anatomist's than from a specialist's point of view.

FRANK J COLE

Zoological Department, Edinburgh, January 12

#### DANTE'S "QUÆSTIO DE AQUA ET TERRA."

"Quæstio Aurea ac perutilis edita per Dantem Alagherum, poetam florentinum clarissimum, de natura duorum elementorum Aquæ et Terræ disserentem."

"Lo, the past is hurled  
In twain up thrust, out staggering on the world,  
Subsiding into shape, a darkness rears  
Its outline, kindles at the core, appears  
Verona"—R. BROWNING, "Sordello," Book 1.

"TO all and each who shall see this document, *Dante Alighieri* of Florence, the least amongst true philosophers, wishes health in Him who is the Beginning of truth and the Light.

"Be it known unto ye all that whilst I was at Mantua there arose a certain question, the which after having been many times dilated upon rather for vain show than for Truth's sake, still remained undecided. Wherefore I, since from boyhood I have been nurtured continually in love of Truth, could not bear to leave the question undiscussed, but I thought fit to show the truth concerning it and to dissolve the arguments adduced to the contrary, both for love of Truth and hatred of Falsehood. And lest the malice of many who are wont to fabricate envious lies against the absent should behind my back alter what was well said, I have moreover thought fit to leave written down on paper what I proved, and to set forth the form of the whole disputation."

These are the words with which Dante commences this "golden and most useful" inquiry concerning the nature of the two elements, earth and water. The treatise is little known in comparison with the other writings of the poet,<sup>1</sup> but although rejected by Ugo Foscolo and others as "impostura indegna d'esame," its genuineness and importance are now almost universally admitted, and without yielding unreservedly to the enthusiastic opinion of an Italian geologist (Stoppani) that there are more truths relating to cosmology to be found prognosticated, affirmed, and even demonstrated in these few pages of the supreme poet than in all the writings of the middle ages taken together, we may nevertheless acknowledge it to be a work of the greatest interest and importance, and by no means unworthy of the singer of the "Divina Commedia."

It seems to be the last work of the poet's life, written at that period which he himself describes in his sonnet to Giovanni Quirino—

"Lo Re, che merta i suoi servi a ristoro  
Con abbondanza, e vince ogni misura,  
Mi fa lasciare la fiera rancura,  
E drizzar gli occhi al sommo consoloro  
E qui pensando al glorioso coro  
De' cittadini della cittade pura,  
Laudando il Creatore, in creatura  
Di più laudarlo sempre m'innamoro."

—Sonetto xlii ed. Fraticelli.<sup>2</sup>

Dante was at this time the guest of Guido Novello di Polenta at Ravenna. About the commencement of the

<sup>1</sup> It is, I believe, the only one of Dante's writings that has not yet been translated into English.

<sup>2</sup> "The King by whose rich grace His servants be  
With plenty beyond measure set to dwell,  
Ordains that I my bitter wrath dispel  
And lift mine eyes to the great consolory  
Till, noting how in glorious quires agree  
The citizens of that fair citadel,  
To the Creator I, His creature, swell  
Their song, and all their love possesses me."

—Rossetti's translation in "Dante and his Circle."

year 1320, he seems to have gone for some unknown reason to Mantua, and there to have entered upon this discussion, which he then completed at Verona. The disputation took place at this latter city on January 20, 1320, as Dante himself tells us, in the church of St. Helena (where in recent years the metropolitan chapter have put up a monument in commemoration of the event). All the clergy of Verona were present, except some few who, in the words of Rossetti—

"Grudged ghostly greeting to the man  
By whom, though not of ghostly guild,  
With Heaven and Hell men's hearts were fill'd"  
—"Dante at Verona."

From a passage which occurs in the course of the treatise, one might almost think that ladies also were present, but let not the reader therefore conclude that the assemblage which listened to Dante's eloquence in that little Veronese temple resembled so many modern philanthropical and other associations in being chiefly composed of ladies and clergymen, for doubtless Can Grande della Scala himself was present to do honour to his former guest, and his poetic fame, which we know to have already spread far and wide, would certainly have brought together as many as the church could hold.

The question to be solved is whether, on any place on the earth's surface, *water* is higher than the *earth*. This question, Dante tells us, was generally answered in the affirmative, and he gives us the five chief reasonings adduced in support of it, of which perhaps the most striking is this one—

"If the earth were not lower than the water, the earth would be entirely without waters, at least in the uncovered part, and so there would be no fountains, nor rivers, nor lakes. So water must be higher than the earth. For water naturally flows downwards, and the sea is the source of all waters, and if the sea were not higher than the earth, the water would not flow to the earth, since in every natural motion the source of the water must be higher."

Another is this—"Water seems chiefly to follow the motion of the moon, as is evident in the flow and ebb of the sea, and therefore since the moon's orbit is eccentric, it seems reasonable that water in its sphere should be eccentric too, and another argument shows that this cannot be unless it be also higher than the earth."

Such be their arguments, but sense and reason alike are against them, and Dante proceeds to explain how he will treat the question. First, he will prove that it is impossible that water in any part of its circumference be higher than this emergent or uncovered earth on which we dwell. Secondly, he will prove that this emergent earth is everywhere higher than the surface of the sea. Thirdly, he will urge arguments against his own demonstrations, and then demolish these objections. Fourthly, the final and efficient cause of the elevation and emergence of the earth will be shown. Fifthly, he will demolish the five chief arguments of the other side which he has already stated.

1. It is impossible that water in any part of its circumference be higher than the earth.

There are only two ways whereby water can thus be higher than the earth—either the water must be *eccentric*, or, if it be *concentric* with the earth, it must be *gibbous* in some part. By water being *eccentric*, Dante means the centre of its natural sphere to be out of and different from the centre of the earth; by being *gibbous*, Dante means some part of its sphere to be raised up so as to form a protuberance or hump, just as he considers the earth on which we live to be a protuberance or gibbosity of the spherical surface of the earth.

He now shows by means of diagrams that neither of these things are possible, but first makes these two statements—(1) Water naturally flows downwards, (2) Water

is by nature a labile body and has not a boundary of its own, but takes the boundary of the thing in which it is contained<sup>1</sup>.

We may compare with this a modern definition of a fluid—

"A perfect fluid is a body whose form can be changed to any extent, provided its volume remain constant, by the application of a stress, however small, if we allow it sufficient time"—Garnett, "Treatise on Heat."

In the first place, *water cannot be eccentric*.

For if it were so, then three impossibilities would follow—(1) Water would naturally flow both upwards and downwards, (2) water would not be moved downwards by the same line as the earth, (3) an equivocation would arise in speaking of the *gravity* of water and of earth, all which things are seen to be not only false but impossible.

The demonstration *ab absurdo* follows thus—Let the heavens be the circumference on which are placed three crosses, water the circumference on which are two, earth the circumference on which is one cross.

Let the centre of heaven and earth be at point A, the centre of water at point B. Thus A, being the centre of the universe, is the lowest spot of all, and everything which has in the world a position alien from A must be higher. Now if there be any water at A and the way be open to it, it will naturally flow to its own centre, B, since it is the property of every heavy body to move to the centre of its own sphere. But the motion from A to B is a motion upwards, therefore water will flow *upwards*, which is impossible.

Again, let there be at Z a lump of earth and some water, and let there be nothing to hinder. Then, since it is the property of every heavy body to move to the centre of its own sphere or circumference, the *earth* will move in a straight line to A, and the *water* in a straight line to B, and this, from the figure, must needs be along different lines. This, says Dante, is not only impossible, but would make Aristotle laugh if he were to hear it.

The third impossibility follows thus.—*Gravity* and *levity* are "passions" of simple bodies which are moved with linear motion, and *light* bodies tend upwards and *heavy* tend downwards, by "heavy" and "light" being meant that which has the power of being moved. If now water moved to B and earth to A, since these are simple bodies and heavy, they will be moved down to different centres. If this were so, the word *gravity* would have an *absolute* signification with respect to earth and *relative* with respect to water. This is what the argument amounts to, and so there would be an equivocation of meaning in the word "gravity."

Therefore, *ab absurdo*, water in its natural circumference is not eccentric or out of the centre common to the circumference of the earth.

In the second place, *water cannot be gibbous*—

<sup>1</sup> "Aqua est labile corpus naturaliter, et non terminabile terminis proprio."—*21*.

Let the heavens be where are four crosses, the water where three, the earth where there are two.

Let D be the centre of *earth* and concentric *water* and *heaven*. Water cannot be concentric with the earth unless the earth be in some part "gibbous" above the central circumference. Let the protuberance of the earth be at G, and at some part of the circumference of water let there be a protuberance of water at H. Then let a line be drawn from D to H and another from D to F, it is manifest

that DH is longer than DF, and therefore the summit of one is higher than the summit of the other. Since both touch at their summit the surface of the water without passing beyond, it is clear that the water of the protuberance will be higher, with regard to the surface where F is. Since, therefore, there is no obstacle, the water of the protuberance will flow down until it become level at D with the central or regular circumference. And thus it will be impossible for a protuberance of water to last or even to exist.—Q E D

Dante now brings forward a subsidiary argument to show that probably water has no protuberance out of the regular circumference. The protuberance of the earth is sufficient to prove and explain everything, and "Quod potest fieri per unum, melius est fieri per unum quam per plura." So there is no protuberance on the surface of the water, because God and Nature always do what is best and do not work in vain.

Since water cannot be eccentric, as was shown by the first figure, nor concentric with a protuberance, as was shown by the second figure, it is necessary that water be concentric and coequal, *i.e.* equally distant in every part of its circumference from the centre of the world.

Thus it has been proved impossible for water in any part of its circumference to be higher than the surface of the earth, and so the first point is completed.

We now pass on to the second.

2. This emergent earth is everywhere higher than the surface of the sea. This is shown in this way.—

All the shores of the ocean, as well as of the Mediterranean seas, rise above the surface of the sea which bounds them, as is clear to the eye. Therefore all the shores are further from the centre of the world, since the centre of the world is also the centre of the sea and the shoreward surfaces are parts of the whole surface of the sea; and since everything that is more remote from the centre of the world is also more high, it follows that the shores everywhere rise above the surface of the sea. And if the shores are higher than the sea, much more must be the other regions of the earth, since the shores are the lower parts of the earth, as we see by the rivers flowing down to them.

3. In accordance with the order of the question as at first stated by Dante, he now brings forward various arguments which seem to contradict his demonstrations, and these arguments he then proceeds to demolish. They need not detain us here. In the course of the operation there occurs a most interesting distinction between *homo-*

*geneous* and *simple* bodies, in which I seem to see a distinct foreshadowing of our modern view of the chemical elements in contradistinction to the ordinary four or five elements of Aristotle and his followers. "*Corpora enim homogenea et simplicia sunt, homogenea ut aurum depuratum, et corpora simplicia, ut ignis et terra*"

§ xviii

But perhaps it might not be out of place to quote here the following passage from G. H. Lewes's "Aristotle"—"One of the great difficulties in interpreting ancient opinions is to guard against the tendency of reading our fulness of knowledge into their vague expressions. We often find in ancient works the precious metal we have ourselves brought with us, as the alchemist often unconsciously put into his crucible the gold, which he afterwards discovered there with surprised delight"—G. H. Lewes, "Aristotle," x § 170.

He thus sets forth the *final* cause of the elevation or emergence of the earth. There must needs be a part in the universe where all *miscibilia*—to wit, elements—can come together, this cannot be unless the earth be in some part emergent. Thus, although earth, according to its own nature, tends always downwards, it has in it another nature by which it obeys the intention of Universal Nature, and allows itself to be here and there raised up, in order that mixture of the elements may be possible, and thence all things that are subject to generation and corruption may be formed.

He further shows that the emergent earth on which we dwell has the form of a semilune, by arguments which he graciously tells us that even ladies can follow—"Manifestum esse potest etiam mulieribus."

4. What now is the *efficient* cause of the elevation or emergence of the earth above the surface of the water?

Dante first shows that neither the *earth* itself, nor *water*, nor *air*, nor *fire* can be the efficient cause. Therefore it must be referred to the *heavens*. But there are many heavens, and to which are we to refer it? Dante shows that it cannot be referred to the *moon*, nor to the heavens of any of the planets (Mercury, Venus, the Sun, Mars, Jupiter, Saturn), nor yet to the Crystalline Heaven or *Primum Mobile*, the 9th sphere. Now, since the only mobile bodies which remain are the Heaven of the Stars, *Cælum Stellatum*, or 8th circle, we must refer the cause of the elevation of the earth of our hemisphere to that. This Heaven of the Stars has at once unity in substance and multiplicity in its virtues or influences, as the poet himself sings—

"Il ciel, cui tanti lumi fanno bello,  
Dalla mente profonda che lui volve  
Prende l'immagine, e fa-sene suggello  
E come l'anima dentro a vostra polve,  
Per differenti membra, e conformate  
A diverse potenzie, si risolve,  
Così l'intelligenza sua bontate  
Moltiplicata per le stelle spiega,  
Girando se sovra sua unitate."

—"Paradiso," ii 130-138.

Dante further refers the elevation of our earth to that region of the *Cælum Stellatum* which roofs over this uncovered earth, that is, that this elevating virtue or influence is in those stars which are in the region of the heaven, which is bounded by the equator and the circle which the pole of the zodiac describes around the pole of the world; "whether it elevate by way of attraction as

"The heaven, which lights so manifold make fair,  
From the Intelligence profound, which turns it,  
The image takes, and makes of it a seal.  
And even as the soul within your dust  
Through members different and accommodated  
To faculties diverse expands itself,  
So likewise this Intelligence diffuses  
Its virtue multiplied among the stars,  
Itself revolving on its unity."  
—"Paradiso," ii 130-138, Longfellow's trans.

the magnet draws the iron, or by way of impulsion, generating impelling vapours, as in certain mountains." A truly scientific and most suggestive remark!

We may compare the last clause with those well-known lines of the "Inferno," in which is described how the earth, and likewise the mountain of Purgatory were formed when Lucifer fell from Heaven —

"Da questa parte cadde giù dal cielo,  
E la terra, che pria di qua si aporse,  
Per paura di lui fe del mar velo,  
E venne all'emisfero nostro e forse  
Per fuggir lui, lasciò qui il luogo voto  
Quella ch'appar di qua, e su ricorse"  
—"Inferno," xxxiv 121-126<sup>1</sup>

But now it may be asked, Since that region of the heaven moveth circlewise, why did not this elevation happen circlewise? Because, Dante answers, the matter was not sufficient for so great an elevation. Then why was the elevation of the earth produced in our hemisphere rather than in the other? To this, says Dante, we must answer as Aristotle does (in "De Cælo," book II) in answer to the question why the heavens move from east to west and not contrariwise, that such questions proceed either from much folly or from much presumption, because they are above our intellect. God made all things for the best, and when He said, "Congregentur aquæ in locum unum et appareat arida," then were the heavens situated to act and the earth potentiated to be passive.

"Let therefore men cease," cries Dante, "yea, cease from inquiring into those things which are above their intellect, and let them strive to the utmost of their power to raise themselves to things immortal and divine, and so leave those things which exceed their understanding. Let them listen to Job — 'Numquid vestigia Dei comprehendēs, et omnipotentem usque ad perfectionem reperiēs.'— (Job xi. 7) Let them hearken to the words of the Psalmist 'Mirabilis facta est scientia tua, et me confortatus es, et non potero ad eam.'— (Ps cxxxviii) Let them hear Isaiah speaking in the person of God to man. 'Quam distant cœli a terra, tantum distant viæ meæ a viis vestris.'— (Is lv 9) Let them hear the voice of the Apostle to the Romans 'O altitudo divitiarum scientiæ et sapientiæ Dei! quam incomprehensibilia judicia ejus, et investigabiles viæ ejus!'— (Rom. xi. 33) Lastly, let them hearken to the very voice of the Creator, saying. 'Quo Ego vado, vos non potestis venire.'— (S. John vii. 34) And let these things suffice for the inquiry of the truth before us."

We may most fittingly compare this Dantesque passage with the close of Galileo Galilei's famous "Dialogo intorno ai due massimi sistemi del mondo, tolemaico e copernicano," which I here venture to translate —

"*Simplicio* If either of you were asked, If God in His infinite power and wisdom could confer upon the element of water the reciprocal movement which we perceive in it, in another way than by the moving of the vessel containing it, I know that you would answer, that He could have done so in many ways, even unimaginable by our intellect, whence I immediately conclude that, this being so, it would be excessive daring for any one to wish to limit and restrict the Divine power and wisdom to a particular phantasy of his own.

"*Salutati*. An admirable and truly angelical doctrine, to which very conformably answers that other divine doctrine, which, whilst it allows us to dispute about the constitution of the world, adds (perhaps in order that the

exercise of human minds be not suppressed nor grow lazy) that we are not to find out the work of His hands. Let therefore the exercise permitted and ordained to us by God make us recognize and so much the more wonder at His greatness, as we find ourselves the less competent to penetrate into the profound abysses of His infinite wisdom.

"*Sagredo* And this will serve for the last conclusion of our four days' argument"—Galileo Galilei, "Dialogo dei Massimi Sistemi, Giornata quarta."

Dante now briefly deals with the five arguments which he mentioned at the beginning of his treatise as the most important against his theory. These being made short work of, he concludes —

"This philosophical question was determined by me, Dante Alighieri, the least of philosophers, beneath the sway of that invincible lord, Messer Cane Grande della Scala, for the holy Roman empire, in the illustrious city of Verona, in the church of S. Helena, and in the presence of all the Veronese clergy, save some few who, aflame with too much charity, do not admit the postulates of others, and through virtue of humility poor of the Holy Spirit, shun being present at their discourses, lest they may seem to approve their excellence.

"Now this was done in the year from the Nativity of our Lord Jesus Christ, 1320, on Sunday, which the Saviour enjoined on us to venerate for His glorious Nativity and His wondrous Resurrection. The which day was the 7th from the ides of January and the 13th before the calends of February" (i.e. January 20).

I have dealt merely with the chief parts of this Dantesque dissertation. According to Signor A. Stoppani ("La questione dell'Acqua e della Terra di Dante Alighieri," in "opp. Lat di Dante," ed. Giuliani, vol. II) there are nine truths relating to cosmology, presaged, affirmed, and in part demonstrated. These nine he makes out thus —

- (1) The moon the principal cause of tides.
- (2) Equality of the sea's level.
- (3) Centripetal force
- (4) Sphericity of the earth
- (5) Dry land simply protuberance of the earth's surface
- (6) Northern grouping together of the continents
- (7) Universal attraction.
- (8) Elasticity of vapours a motive power
- (9) Heaving up of the continents

Let me now add a tenth. A vague foreshadowing of our modern idea of chemical elements as distinct from those of Aristotle, or at least of homogeneous chemical bodies, "Corpora enim homogenea et simplicia sunt, homogenea, ut aurum depuratum; et corpora simplicia, ut ignis et terra." EDMUND G. GARDNER

Calus College, Cambridge

### MOROCCO.<sup>1</sup>

MOROCCO has a paradoxical place in the history of exploration, although the only part of Africa fully in sight from the shores of Europe, and dotted with one or two half European coast towns, its interior is more firmly closed to the traveller, sportsman, and missionary than the dense forests of the Congo, or even the shores of Lake Chad. The difficulties in the way are not physical, nor are they wholly political. They arise mainly from the deeply-rooted antagonism in race and creed between the inhabitants of Morocco and all Christendom — this quaint and semi-fossil phrase is still here a necessary and sufficient term. At this moment public atten-

<sup>1</sup> "Upon this side he fell down out of heaven;  
And all the land, that whilom here emerged,  
For fear of him made of the sea a veil,  
And came to our hemisphere, and peradventure  
To flee from him, what on this side appears  
Left the place vacant here, and back recoiled."  
—"Inferno," xxxiv. 121-126, Longfellow's trans.

<sup>1</sup> "Bibliography of the Barbary States." Part IV. A Bibliography of Morocco from the earliest times to the end of 1891. By Lieut. Col. Sir R. Lambert Playfair and Dr. Robert Brown.

tion is turned somewhat intently on the political conditions of the Oriental despotism which has so anomalously maintained itself to the west of our prime meridian. Hence the politician has a temporary interest in what would otherwise have appealed mainly to the geographer and man of science, the publication by the Royal Geographical Society of a "Supplementary Paper," the "Bibliography of Morocco." This is a work of splendid thoroughness, almost, if not quite, exhaustive in its list of 2243 titles, and made convenient for reference by two copious indexes of subjects and authors. But it is much more than a catalogue. Comments, judiciously brief, but in some cases of exceptional interest extending to a couple of pages, give information as to little-known authors, or record some striking circumstance in or concerning the books referred to. There is a specially-compiled map, and an introduction which is really an essay on the growth of knowledge regarding Morocco in European countries. With regard to the map, it is explained that only the coast-line has been surveyed. As to the interior—

"The best mapped districts are laid down solely from running *reconnaissances* or sketch-maps. Positions fixed by astronomical observations are few. Many wide areas have never been visited by any Europeans, and most of the Atlas is at this hour as little known as it was in the days of Leo Africanus. There are cities within a few hours' ride of Tangier, which no person capable of giving a correct account of his observations has visited, and there are others not much farther away, to attempt to enter which—Zarhoun, for example—would, were the intruder detected, be certain death. There is scarcely a river laid down with even approximate accuracy, and, not to enumerate more distant provinces, the entire Riff country, that bold *massif* which is familiar to the thousands who every year sail up and down the Mediterranean, is less explored than many regions in the centre of the continent."

The present population of Morocco is a puzzle almost as difficult, although on a smaller scale, as that of China. The authors of the Bibliography give 4,000,000 as an estimate, but the guesses of various authorities vary between 1½ and 15 millions. The roads shown on the map are mere mule and camel tracks made by the feet of the pack-animals, unaided by any engineer. Ferries are rare, and, of course, bridges are unknown in the interior. The distribution of towns and villages is often at variance with the rules holding for civilised countries. The villages are built out of the way of the main tracks, because people never travel in Morocco for the good of the inhabitants, and it is safer to live off the path of the tax-collector and the Government official, who demands free food and quarters. The great number of place-names on the map of so thinly-peopled a country is due to the fact that the tombs of saints are such important landmarks that they must be indicated, even if only a few persons live beside them. "All the places beginning with 'Sidi' (Lord, master) are either actually tombs or the tomb has formed, as in so many of our cathedral cities, the nucleus of the town or village." "Sok," another affix of frequent occurrence, means market-place, and many of the established sites for periodical fairs are uninhabited between the gatherings of people from far and near. Many of the place-names on the coast exist in two forms at least—the native word and its Portuguese or Spanish translation, Casablanca and Dar-el-beida (both meaning White house) for example. We regret that the authors did not see their way to lay down precise rules for the spelling of Moorish place-names, either by giving a standard transliteration of the Arabic, or a uniform phonetic system. Indeed, even in the introduction a few anomalous spellings are found, e.g. *Zarhoun* and *Zerkun*, *Moulai* and *Moulas*.

The physical geography of Morocco appears to be

changing, and the natural conditions of the country are less favourable for agriculture than they were a few centuries ago. The forests have been destroyed with such recklessness that the soil has been dried up and swept away in many places; there is evidence that the rainfall has diminished, lakes have dried, and rivers formerly navigable have become silted up, or alternate as dry tracts of stone and raging torrents.

In one respect alone—the enthusiastic Moslemism of its people—does Morocco show no sign of degeneration. Although the Moors can no longer seize and hold the Christian slaves, whose stories bulk so largely in the bibliography, their hatred and contempt towards "unbelievers" is in no sense abated. Into such a land no Europeans could penetrate far, except in the past as slaves, or now as official messengers of European Powers under special protection, jealously watched and prevented from studying places or people. The last serious attempt at scientific exploration—that of Mr Joseph Thomson—was again and again almost stopped by the fanatical Kaid, and only his remarkable persistence and daring stratagems carried him as far as he reached. Such stratagems would hardly serve again, and for the present the exploration of the Atlas Mountains, with their half-guessed topography, imperfectly known flora, and unsurveyed mineral wealth is at an end. The futility of disguise as an aid to exploration is fully proved in the records before us, where the ghastly fate of many who tried to pass as Moslems, and the unsatisfactory results obtained by others who escaped alive, are briefly told.

It seems to us that an attempt might well be made to open communications with fanatical Mohammedan countries either by explorers or diplomatic agents of the same faith, and there must be many amongst the educated Mohammedans of India who are well suited for such work. The religious beliefs of a people with whom belief and conduct are so closely related, must be taken into account in dealing with them, just as much as the physical features of a country. And as Arctic sailors have been proved to be the natural explorers in the Antarctic seas, Swiss mountaineers the safest pioneers on New Zealand glaciers, and Canadian boatmen the most expert in shooting the Nile cataracts, so Mohammedan envoys might be expected to make the most favourable impression on the people of Morocco or of the Mohammedan Sudan.

Sir Lambert Playfair and Dr Brown deserve the heartiest thanks for completing their Bibliography of the Barbary States in such an admirable way, and we do not doubt that the work will be very widely consulted in the immediate future.

#### THE RATE OF EXPLOSION IN GASES

THE following is an abstract of the Bakerian Lecture on "The Rate of Explosion in Gases," delivered before the Royal Society by Prof Harold B Dixon, on January 19.—

1 Berthelot's measurements of the rates of explosion of a number of gaseous mixtures have been confirmed. The rate of the explosion wave for each mixture is constant. It is independent of the diameter of the tube above a certain limit.

2 The rate is not absolutely independent of the initial temperature and pressure of the gases. With rise of temperature the rate falls, with rise of pressure the rate increases; but above a certain *critical pressure* variations in pressure appear to have no effect.

3. In the explosion of carbonic oxide and oxygen in a long tube, the presence of steam has a marked effect on the rate. From measurements of the rate of explosion with different quantities of steam, the conclusion is drawn that at the high temperature of the explosion wave, as

well as in ordinary combustion, the oxidation of the carbonic oxide is effected by the interaction of the steam.

4 Inert gases are found to retard the explosion wave according to their volume and density. Within wide limits an excess of one of the combustible gases has the same retarding effect as an inert gas (of the same volume and density), which can take no part in the reaction.

5 Measurements of the rate of explosion can be employed for determining the course of some chemical changes.

In the explosion of a volatile carbon compound with oxygen, the gaseous carbon appears to burn first to carbonic oxide, and afterwards, if oxygen is present in excess, the carbonic oxide first formed burns to carbonic acid.

6 The theory proposed by Berthelot—that in the explosion wave the flame travels at the mean velocity of the products of combustion—although in agreement with the rates observed in a certain number of cases, does not account for the velocities found in other gaseous mixtures.

7 It seems probable that in the explosion wave—

(1) The gases are heated at *constant volume*, and not at *constant pressure*;

(2) Each layer of gas is raised in temperature *before* being burnt;

(3) The wave is propagated not only by the movements of the burnt molecules, but also by those of the heated but yet unburnt molecules;

(4) When the permanent volume of the gases is changed in the chemical reaction, an alteration of temperature is thereby caused which affects the velocity of the wave.

8 In a gas, of the mean density and temperature calculated on these assumptions, a sound wave would travel at a velocity which nearly agrees with the observed rate of explosion in those cases where the products of combustion are perfect gases.

9 With mixtures in which steam is formed, the rate of explosion falls below the calculated rate of the sound wave. But when such mixtures are largely diluted with an inert gas, the calculated and found velocities coincide. It seems reasonable to suppose that at the higher temperatures the lowering of the rate of explosion is brought about by the dissociation of the steam, or by an increase in its specific heat, or by both these causes.

10. The propagation of the explosion wave in gases must be accompanied by a very high pressure lasting for a very short time. The experiments of MM Mallard and Le Chatelier, as well as the author's, show the presence of these fugitive pressures. It is possible that data for calculating the pressures produced may be derived from a knowledge of the densities of the unburnt gases and of their rates of explosion.

#### NOTES.

THE forty-sixth annual general meeting of the Institution of Mechanical Engineers will be held on Thursday evening and Friday evening, February 2 and 3, at 25, Great George Street, Westminster. The chair will be taken by the president, Dr. William Anderson, F.R.S., at half past seven on each evening. The annual report of the council will be presented to the meeting on Thursday, and the annual election of the president, vice-presidents, and members of council, and the ordinary election of new members will take place on the same evening. The following papers will be read and discussed, as far as time permits:—Description of the Experimental Apparatus and Shaping Machine for Ship Models at the Admiralty Experiment Works, Haslar, by Mr. R. Edmund Froude, of Haslar (Thursday); description of the Pumping Engines and Water-Softening

Machinery at the Southampton Water Works, by Mr. William Matthews, Waterworks Engineer (Friday).

PROF. CAYLEY, we are glad to learn, is now convalescent.

We greatly regret to have to announce the death of Mr. H. F. Blanford, F.R.S. He died on Monday at the age of fifty-eight.

PROF. MICHAEL FOSTER, Sec. R.S., has been appointed Rede Lecturer at Cambridge for the present term. His Rede lecture will be delivered early in June.

THE Bill for the introduction of a standard time (mean solar time of the fifteenth meridian) was read a second time in the German Imperial Parliament on Monday. The measure was accepted without much discussion.

AN excellent report on technical education in London has been submitted to the London County Council by a special committee appointed to investigate the subject. The report was prepared by Mr. Llewellyn Smith, the committee's secretary, and displays a thorough grasp of the essential conditions of the problem. It is proposed that a Technical Instruction Board shall be appointed, and that it shall consist of some members of the Council, and of representatives of the School Board, the City and Guilds of London Institute, the City Parochial Charities, the Head Masters' Association, the National Union of Elementary Teachers, and the London Trades Council. The committee think that one third of the amount derived from the beer and spirits duties should be handed over to this body for the provision of adequate technical instruction in all parts of London.

THE French Minister of the Interior has established at Marseilles, in connection with the university, an institute for botanical and geological research, and a museum. The director is Prof. Heckel, who, as well as a curator and a librarian, gives his services gratuitously.

In the year 1793 was published Christian Konrad Sprengel's "Das entdeckte Geheimnis der Natur im Bau und in der Befruchtung der Blumen," the work which first directed the attention of naturalists to the contrivances which, in many flowers, render self-pollination difficult, and promote the visits of insects to assist cross-pollination. The copper-plate illustrations of this work still maintain their character as among the best that have been published in this branch of science. Sprengel was in many respects a forerunner of Darwin, and centenaries have been celebrated on slighter grounds than the publication of this work.

THE chief characteristics of the weather during the past week have been its general mildness and dampness, the day temperatures have at times exceeded 50° in most parts of the kingdom, but at night slight frosts occurred towards the end of last week in Scotland and the south-eastern parts of England. The distribution of pressure has been complex, a series of depressions have passed over the coast of Norway from the westward, while an anticyclone lay over the south-western parts of our islands, the reading of the barometer in the south-west being about an inch higher than in the north of Scotland. The passage of the low-pressure systems in the north was accompanied by strong north-westerly winds and gales in Scotland, with hail or sleet in many places. Owing to the disappearance of the anticyclone from the continent, north-westerly winds became prevalent over western Europe, and a rapid rise of temperature occurred there, amounting to 30° in Germany between the 20th and 21st instant. During the last few days fresh depressions have approached our north-western coasts, with increasing winds from the south-west, and

a continuance of mild, unsettled weather appeared probable. The *Weekly Weather Report* shows that for the week ending the 21st instant there was a large deficiency of rainfall in the west of Scotland, south-west of England, and south of Ireland. The percentage of possible duration of sunshine ranged from 28 in the south-west of England to 7 in the south of England and to 3 in the north of Scotland.

THE *Repertorium für Meteorologie*, vol. xv recently issued by the Imperial Academy of Sciences of St Petersburg, contains a discussion by P. A. Muller, of the Ekaterinburg Observatory, at the foot of the Ural Mountains, in the Government of Perm, on the question of the evaporation from a snow surface. Several writers, among whom are Drs Bruckner and Woeikof, differ in opinion as to whether the evaporation from a snow surface exceeds the condensation of the aqueous vapour of the air immediately above it. The method generally adopted for the decision of the question is to find whether the temperature of the snow surface is above or below the dew-point of the surrounding air, in one case there would be evaporation, and in the other condensation. The paper occupies forty seven small folio pages, and the observations were made hourly from December 21, 1890, to February 28, 1891. The result of the investigation shows that according to the temperatures of the dew-point and of the surface of the snow, the evaporation of the snow greatly exceeds the condensation of the aqueous vapour, for the condensation occurred at only 27 per cent while the evaporation occurred at 73 per cent of the hourly observations.

PROF FLINDERS PETRIE, to whose introductory lecture at University College, Gower Street, we referred last week, delivered on Saturday the first of his regular course of lectures on the Edwards Foundation. He said the Egypt of the early monuments was a mere strip of a few miles wide of green, amid boundless deserts, and beneath a sky of the greatest brilliancy, a land of extreme contrasts of light and shadow, of life and death. These conditions were reflected in the art. On the one hand was the most massive and overwhelming construction, and, on the other, the most delicate and detailed reliefs. On the one hand, the most sublime and stolid statuary, on the other, the course and accidents of daily life freely treated. On the one hand, masses of smooth buildings that far outdo the native hills on which they stand, gaunt and bare, and, on the other, the vivid and rich colouring in the interiors. In consequence of the climate also Egypt is a land of great simplicity of life, and simplicity is especially the characteristic of the oldest Egyptian buildings. Speaking of the early Egyptian statuary, Prof. Petrie said that the race represented by them appears as "one of the noblest that ever existed."

At Leeds, on Monday, Lord Playfair presided at a public dinner, held in support of the Yorkshire College. In proposing the principal toast—"The Yorkshire College"—he spoke of the efforts made half a century ago to secure for science the place which rightly belongs to it in the educational system. He was glad, he said, that these efforts had met with a temporary resistance, because if the Universities had at once yielded there would have been no colleges now in our great provincial towns. The colleges, he thought, were adapting themselves rapidly and well, upon the whole, to the genius of their several localities. Of the Yorkshire College he said that she had fitted herself for the liberal culture and life-work of a great industrial centre. "No doubt her technical courses are peculiar. Actual laboratories for spinning, for dyeing, for tanning, for engineering, are novel adjuncts to a college. What does it mean? That you are trying to strengthen and embellish industrial pursuits, as the Universities acted upon the professions when they were obliged to include them. Surely a great town like Leeds is right when

it imbues its producers with intellectual knowledge, as well as with technical expertise. Such men in future carve out industrial professions for themselves, and illumine them by appropriate culture."

THE interesting address lately delivered by Sir Henry Roscoe on the occasion of the prize distribution at the Birmingham Municipal Technical School has now been issued separately. He describes the report of the first year's work as "more than encouraging." Speaking of the building which is to be erected for technical training at Birmingham, he says—"You in Birmingham have, in my judgment, taken the right course. You are not going to squander your money by using it for a thousand different purposes. You are, I hope, going to do a good thing, and a big thing, in building and equipping a really great institution, worthy of your city and of your well-earned renown as being foremost amongst our towns in educational matters. You will have a place of higher technical instruction to which all the Midlands will look up. It will be the gathering ground for all the youthful talent of the busy millions of the district. It will be here that the future Faradays, and Priestleys, and Watts will get that sound though elementary scientific training which will enable them to pursue that training to its highest point at the Mason College here, or in other colleges elsewhere, which may in the end make both them and their country great."

THE new technical schools connected with University College, Nottingham, which were formally opened the other day, promise to be of immense service, not only to Nottingham itself, but to the wide district of which it is the educational centre. A remarkably clear description of the buildings, with plans, is given in a pamphlet prepared for the ceremonial opening. The pamphlet also includes an interesting summary of the facts relating to the history of the Nottingham College and its technical department.

MR. C. F. JURITZ, Senior Analyst in the Department of Lands, Mines, and Agriculture, Cape Colony, announces in the *Agricultural Journal*, issued by the Department, that a comprehensive series of investigations with reference to the chemical composition of the various soils of the colony is about to be undertaken. The samples of soil are to be collected by one of the officers of the analytical branch of the Department. In the first instance the southern part of the Malmesbury district will be visited, and soils will be taken from several localities representative (a) of primary and (b) of alluvial soils belonging to the Malmesbury beds of clay slate. Mr. Juritz proposes next to collect soils from the more northerly portion of the same district, in the vicinity of Hopefield, for instance, after which the Caledon district will be taken in hand. These analyses when completed will afford, he points out, an insight into the general composition of the clay slate soils, lying around the south-western coast of the Colony between Donkin's and Mossel Bays. The Government of Cape Colony look upon the proposals that have been made as "a move in the right direction," and have promised their warmest support.

MR. KEDARNATH BASU, describing in *Science* some relics of primitive fashions in India, says he does not see the same profusion as he saw ten or twelve years ago, of tattoo-marks and red-ochre or red oxide of lead (*madur*) over the forehead and crown among the women of Bengal. The rapid progress of female education and the consequent refinement in æsthetic taste are, he says, the causes of the decline of this rude and savage adornment. The people of Behar, the North-western provinces, and other districts, however, still cling to these remnants of savagery. The up-country women, besides tatooing their bodies and painting the head with red paint, bore the lower lobes of their ears,

and insert big and heavy wooden cylindrical plugs, which almost sever the lobes from the ears. The plugs are sometimes as big as two inches in length with a diameter of an inch and a half, and as much as two ounces in weight. These heavy plugs pull down the lobes of the ears as far as the shoulders, and give the wearers a hideous look.

MR F J BLISS contributes to the new "Quarterly Statement" of the Palestine Exploration Fund a most interesting report on the excavations at Tell-el Hesi during the spring season of 1892. Speaking of the now famous tablet discovered in the course of these excavations, he says:—"On Monday, May 14, ten days before we closed the work, I was in my tent at noon with Ibrahim Effendi, when my foreman Yusif came in with a small coffee-coloured stone in his hand. It seemed to be curiously notched on both sides and three edges, but was so filled in with earth that it was not till I carefully brushed it clean that the precious cuneiform letters were apparent. Then I thought of a day, more than a year before, when I sat in Petrie's tent at the pyramid of Meydûn, with Prof Sayce. He told me that I was to find cuneiform tablets in the Tell-el Hesi, which as yet I had never seen, and gazing across the green valley of the slow, brown Nile, and across the yellow desert beyond, he seemed to pierce to the core, with the eye of faith, the far away Amorite mound. As for me, I saw no tablets, but I seemed to be seeing one who saw them." Mr Bliss also notes that the discovery was a triumphant vindication of Mr Flinders Petrie's chronology—established, not by even a single dated object, but by pottery, mostly plain and unpainted. It is announced in the "Quarterly Statement" that the excavations at Tell el Hesi are now being vigorously carried on by Mr Bliss, who has recovered from his serious illness.

It seems that in Yucatan and Central America, as in Egypt and other countries, ancient monuments are held in small respect by certain classes of travellers. According to Mr. M. H. Saville, assistant in the Peabody Museum, who writes on the subject in *Science*, enormous damage is being done to many of the most interesting antiquities in these regions. The magnificent "House of the Governor" in Uxmal, described as probably the grandest building now standing in Yucatan, is almost covered with names on the front and on the cemented walls inside. These names are painted in black, blue, and red, and among them are the names of men widely known in the scientific world. The "House of the Dwarfs" in the same city has suffered in like manner, and many of the sculptures which have fallen from the buildings in Uxmal have been wilfully broken. In Copan, when the Peabody Museum Honduras Expedition compared the condition of the "Idols" to day with the photographs taken by Mr A P Maudslayi seven years ago, it was found that during that time some of the very finest sculptures had been disfigured by blows from machetes and other instruments. The Stela given as a frontispiece in Stephens' "Incidents of Travel in Central America," vol. 1., has been much marred by some one who has broken off several ornaments and a beautiful medallion face from the northern side. One of the faces and several noses have been broken off from the sitting figures on the altar figured by Stephens in the same volume, opposite page 142, and on some of the idols and altars names have been carved. While excavating in one of the chambers of the Main Structure, members of the Expedition uncovered a beautiful hieroglyphic step, but before they had time to secure a photograph of it, some visitor improved the opportunity while no one was about to break off one of the letters. In Quirigua a small statue, discovered by Mr. Maudslayi and removed by him to a small house near the rancho of Quirigua, had the head and one of the arms broken from it during the interval between two visits. This statue was of the

highest importance, as it very much resembled the celebrated "Chaac-mol" now in the Mexican Museum, but discovered by Le Plongeon at Chichen Itza. Much mischief is also done by natives, who think nothing of tearing down ancient structures in order to provide themselves with building materials. The authorities of the Peabody Museum, to whom the care of the antiquities of Honduras has been granted for a period of ten years, deserve much credit for the efforts they make to cope with the evil. They have caused a wall to be built round the principal remains in Copan, and a keeper has been placed in charge with strict orders to allow nothing to be destroyed or carried away.

WHAT is the true Shamrock? Most Irishmen are probably of opinion that they can answer the question correctly, but unfortunately they do not all give the same reply. Mr Nathaniel Colgan, who has been investigating the subject, collected thirteen specimens from the following eleven counties—Derry, Antrim, Armagh, Mayo, Clare, Cork, Wexford, Wicklow, Carlow, Queen's County, and Roscommon. Shamrocks were thus secured from northern, southern, eastern, western, and central Ireland, Mr. Colgan's correspondents in the various counties taking pains to have each sample selected by a native of experience who professed to know the genuine plant. All the specimens were planted and carefully labelled with their places of origin, and flowering within some two months later gave the following results: eight of the specimens turned out to be *Trifolium minus* of Smith, and the remaining five *Trifolium repens* of Linnæus. Cork, Derry, Wicklow, Queen's County, Clare, and Wexford declared for *Trifolium minus*, Mayo, Antrim, and Roscommon for *Trifolium repens*, and Armagh and Carlow, each of which had sent two specimens, were divided on the question, one district in each county giving *T. repens*, while the other gave *T. minus*. These results are set forth by Mr Colgan in an interesting paper in the first volume of the *Irish Naturalist*, to which we referred last week. Elsewhere in the same volume Mr R L Præger suggests that authentic specimens of shamrock should be obtained from every county in Ireland, and he adds that he has no doubt Mr. F W. Moore would gladly grow them at Glasnevin Gardens, if Mr Colgan did not care to undertake so large an order. Mr Præger notes that in his own district, North Down, *Trifolium minus* is always regarded as the true shamrock, but that a luxuriant specimen, or one in flower, is generally discarded as an impostor.

THE waters of the Great Salt Lake, Utah, are known to vary in salinity at different times. Dr Waller, of Columbia College, gives the results of his recent determination of the dissolved salts in the *School of Mines Quarterly*. A comparison of his results with those obtained by Gale, Allen, Bassett, and others, shows a constant change of salinity, and a closer examination reveals a variation from place to place. This is due to local differences in the amount of evaporation, and to the influx of water, fresh or saline, in many cases from subterranean springs which give no indication of their presence. For some of the constituents the water is nearly at saturation point, and differences of temperature are also apt to cause slight differences of composition. The presence of lithium and bromine strengthens Captain Bonneville's conclusions with regard to the basin of the ancient lake called after his name, and now represented by the Great Salt Lake and its lesser neighbours. The benches of sand and gravel seen high up on the flanks of the Wahatch mountains and the Ogilvie range indicate the eastern and western shores of the old lake, whose waters must have covered an area equal to that of Lake Haron, or ten times that of the Great Salt Lake. Successive lowerings of level finally cut off its outlet to the north, by which it used to flow into the Pacific Ocean.

A BEAUTIFUL optical phenomenon, which has not yet been satisfactorily explained, is described by M F Folie in the *Bulletin* of the Belgian Academy. It was observed about a mile from Zermatt on August 13 at 8.30 a.m. "On our right, towards the east, on the steep flanks of the mountains which enclose the valley of the Viège, rose a group of fir trees, the highest of which projected themselves against the azure of the sky, at a height of 500 m above the road. Whilst I was botanising my son exclaimed 'Come and look the firs are as if covered with hoar-frost.' We paid the most scrupulous attention to the phenomenon. To make sure that we were not misled by an illusion we made various observations, both with the naked eye and with an excellent opera glass." It was observed that not only the distant trees, but those lining the road, glittered in a silvery light, which seemed to belong to the trees themselves, and that the insects and birds playing round the branches were bathed in the same light, forming an aureole round the tops of the trees, somewhat resembling the light effects observed in the Blue Grotto. It is suggested that the light was reflected from the snow. Since it disappeared as soon as the sun rose above the hill, and has never been seen except in the presence of snow, this explanation appears plausible, but it is highly desirable that further and more detailed observations should be made of this *spectacle féerique*.

THE Tasmanian Official Record is henceforth to be issued tri-annually instead of annually, and a handbook has been issued to take its place during the intervening years. This handbook (which is described on the title-page as "for the year 1892") contains a brief epitome of the historical portion of the Official Record, and summarises in a convenient form the more important statistical information contained in the detailed tables of the last volume of the general statistics of the colony.

MESSRS ASHER AND CO. will publish shortly an English translation of the "Recollections of the Life of the late Werner von Siemens," the well known electrician, and brother of Sir William Siemens. Two editions of the German original, published in December last, were issued in the course of a few weeks.

THE course of four winter lectures in connection with the London Geological Field Class will this year be delivered by Prof H G Seeley, F.R.S., on Tuesday evenings, at the Memorial Hall, Farringdon Street, the subject being "The Fossil Reptiles of the Thames Basin." All particulars may be had of the Hon Sec Mr J. H. Hodd, 30 and 31, Hatton Garden, E.C.

THE bacterial purification which takes place in a river during its flow has been recently attributed in part to the process of sedimentation which the micro organisms in the water undergo, but it would seem that yet another factor must be taken into account. Buchner, in some investigations which he has recently published ("Ueber den Einfluss des Lichtes auf Bakterien," *Centralblatt für Bakteriologie*, vol 11, 1892, also vol 12, p. 217) shows that this diminution of the numbers present may be also assisted by the deleterious action which light exercises upon certain micro-organisms. A systematic series of experiments was made by introducing typhoid bacilli, *B. coli communis*, *B. pyocyaneus*, Koch's cholera spirilla, also various putrefactive bacteria, into vessels containing sterilized and non-sterilized ordinary drinking water. As a control, in each experiment one vessel thus infected was exposed to light, whilst a second was kept under precisely similar conditions, with the exception of its being covered up with black paper, by means of which every particle of light was excluded. The uniform result obtained in all these experiments was that light exercised a most powerful bactericidal action upon the bacteria in the water under observation. For example, in one water in which at the commencement of the experiment 100,000 germs of *B. coli communis* were present

in a c.c., after one hour's exposure to direct sunlight none were discoverable, whilst in the darkened control flask during the same period a slight increase in the numbers present had taken place. Even the addition of culture fluid to the flasks exposed to sunlight could not impair in the least the bactericidal properties of the sun's rays. In the flasks exposed to diffused daylight the action was less violent but still a marked diminution was observed. In his later experiments Buchner has employed agar-agar, mixing a large quantity of particular organisms, pathogenic and others, with this material in shallow covered dishes and then exposing them to the action of light and noting its effect upon the development of the colonies. For this purpose strips of black paper cut in any shape (in the particular dish photographed by Buchner letters were used) were attached outside to the bottom of the dish, which was then turned upwards and exposed to direct sunlight for one to one and a half hours and to diffused daylight for five hours. After this the dish was incubated in a dark cupboard. At the end of twenty-four hours the form of the letters fastened to the bottom of the dish was sharply defined, the development of the colonies having taken place in no part of the dish, except in those portions covered by the black letters. Some interesting experiments on the same subject have also recently been made by Kotljars (*Centralblatt für Bakteriologie*, December 20, 1892). In the course of these investigations the author found that of the coloured rays of the spectrum the red favoured the growth of those bacteria experimented with, whilst the violet rays acted prejudicially, although less so than the white rays. The exceedingly interesting observation was made that the violet rays actually favoured the sporulation of the *Bac. pseudo-anthraxis*.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr A. Sandbach, a Triton Cockatoo (*Cacatua triton*) from New Guinea, presented by Mr Arthur Harter, a Gannet (*Sula bassana*) British, presented by Mr F W. Ward, two Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, presented by Mr W H Purvis, two Wanderoo Monkeys (*Macacus silenus*) from the Malabar Coast, a Straw-necked Ibis (*Carphibis spinicollis*) from Australia, four Snow Buntings (*Plectrophanes nivalis*), six Wild Ducks (*Anas boschas*, 3 ♂ 3 ♀) British, purchased, a Meadow Bunting (*Emberiza cia*) European, received in exchange, two Shaw's Gerbilles (*Gerbillus shawi*) born in the Gardens.

#### OUR ASTRONOMICAL COLUMN

COMET HOLMES.—*Edinburgh Circular*, No 37, announces that Palisa, telegraphing from Vienna, states that Comet Holmes now resembles an 8 m star with a nebulous envelope 20" of arc in diameter.

A further observation made by Prof. Schur in Göttingen on January 19 showed that the nucleus was of the 10th magnitude, and could not be considered at all brighter than that magnitude. For the latter observation the air, as regards clearness, was all that could have been desired.

At South Kensington, on January 18, the comet was observed as a hazy star and estimated to be about the 8th magnitude.

The following ephemeris is that given by Schulhof—

Date	R.A. app. h. m. s.	Decl. app.
Jan 26 ...	1 35 33.0	+33 42 3
27 ..	36 58.7	42 51
28 ..	38 25.1	43 44
29 ..	39 52.1	44 43
30 ..	41 19.8	45 46
31 ..	42 48.1	46 55
Feb 1 ..	44 17.0	48 8
2 ..	45 46.5	33 49 26

On January 30 the comet will lie very nearly between  $\beta$  Andromedæ and  $\beta$  Trianguli, about one-third of the distance from the latter star.

COMET BROOKS (NOVEMBER 19, 1892) —The following ephemeris of Comet Brooks is due to Ristenpart, and is given in *Astronomische Nachrichten*, No 3142 —

1893	R. A. (app.) h m s	Decl (app) ° ' "	Log r	Log Δ	Br
Jan. 26	23 35 8	+40 34 3	0 0921	0 0471	2 94

Feb. 1	54 14	35 13 1	0 1015	0 1101	2 11
2	23 56 48	34 27 7			

This comet, which will be found to be in the constellation of Andromeda, will lie about  $3\frac{1}{2}^{\circ}$  to the south of  $\alpha$  Andromedæ on January 27

PHOTOGRAPHIC ABSORPTION OF OUR ATMOSPHERE —The question of the degree with which our atmosphere absorbs photographic rays has become very important owing to the adoption of photography, so that any work enlightening us on this subject is anxiously listened to. Prof Schaeberle, who has been making investigations in this direction, has just completed a memoir which is being published by the University of California, but in the meanwhile he has issued a table setting forth simply the final results. The absorption in the following table is expressed in photographic magnitudes, and must be added to the unknown atmospheric absorption at the zenith

Z D	Phot Absorp	Z D	Phot Absorp

HARVARD COLLEGE OBSERVATORY.—The forty-seventh annual report of this Observatory, by Prof Pickering, opens with a reference to the death of Mr George B. Clark, to whose "genius for mechanical devices, indomitable perseverance, and devotion to the interests of the observatory, we are indebted for the success of many of our most useful instruments." Of the most important matters mentioned in the report are the permanent establishment of an observing station in South America, where the unsteadiness of the air is for the most part eliminated, the construction of a suitable building for the housing of photographs and the approaching completion of the Bruce photographic telescope. The work done with the various instruments during this period has been considerable. With regard to the Draper telescope, as many as 2777 photographs have been taken, while those taken with the Bache instrument number nearly 2000. The Boyden department, which is situated at Arequipa, in Peru, has been making great progress, the results of which have been frequently inserted in *Astronomy and Astrophysics*. The eight surfaces of the objective of the Bruce telescope have, as Prof Pickering informs us, been ground and polished, and the results up to the present, according to tests made on a star, are very satisfactory. This instrument, when finished, is destined for the Arequipa station.

SOLAR OBSERVATIONS AT ROME —Prof. Tacchini has issued the results of the observations made with regard to the distribution in latitude of the solar phenomena at the Royal Observatory during the third semester in 1892. From the tabulated statement which he gives the following facts may be gathered.

With regard to the eruptions, these phenomena seem to be quite local to the equatorial regions, the relative frequency being 0.667 and 0.333 for the north and south latitudes respectively. The spots, faculæ, and eruptions have their maxima nearly at the same distance from the equator both north and south, the zones being ( $\pm 20^{\circ}$ ,  $\pm 30^{\circ}$ ), but the maxima for the prominences extend further north, about latitudes  $60^{\circ}$  north and south. Prof. Tacchini remarks that in the equatorial zone ( $+20^{\circ}$ — $-20^{\circ}$ ), where the maxima of faculæ, spots, and eruptions are observed, a feeble relative frequency in the prominences is noted, which shows us that we must consider a large number of prominences as the result of conditions "bien différentes par rapport à celles qui déterminent la production des taches

dans la photosphère," whilst the prominences are formed simply in the solar atmosphere. As a case in point, he mentions an observation made on August 1 of last year, of a cloud which, starting at a distance of  $264''$ , rose to  $364''$  without any corresponding alteration at the surface.

THE TOTAL SOLAR ECLIPSE, APRIL 15-16, 1893 —Writing to M. Flammarion about the scientific expedition sent by the Brazilian Government to study the region of the central plateau and to select a site for the proposed new capital, Dr Cruls, the Director of the Observatory at Rio de Janeiro, adds the following note —"About the total eclipse of April 16. Will France send any one to observe it? I beg you to make known through the *Revue (L'Astronomie)* that the Brazilian Government is willing to send a warship to Ceara, on which foreign astronomers who wished to observe the phenomenon could find a passage."

### GEOGRAPHICAL NOTES

A CHANGE has been made in the arrangements for the expedition to Lake Rudolf referred to on p 235, vol. xlvii. The expedition is to travel by the Tana river instead of the Juba, although its ultimate destination is the same, and Lieutenant Villiers, instead of accompanying it, has joined Sir Gerald Portal's mission to Uganda.

MR H J MACKINDER, M A, Reader in Geography at Oxford, delivered the first of a course of ten educational lectures, under the auspices of the Royal Geographical Society, on the relation of geography to history, on the 20th inst. The attendance was largely composed of teachers and University Extension students, to whom special terms were offered. The lecturer treated of "the Theatre of History," tracing the development of accurate geographical knowledge from the earliest times in a series of brilliant generalisations. He dwelt upon the contrast between the knowledge of early Greek geographers regarding the true shape of the earth, and their habitual representation of the regions known to them in a circular form. In the middle ages, amongst the half-learned, the map of the known world was elevated to the highest place, the figure of the globe was forgotten, and the doctrine of a flat earth gained currency. At the geographical renaissance the map was adapted once more to the sphere, and the discoveries of Columbus and his contemporaries resulted directly.

THE suggestion of Mr Joseph Thomson to bestow the name of Livingstonia (vol. xlvii p 160) on the British sphere of influence north of the Zambesi, in spite of its singular propriety, has, we fear, failed to convince the authorities in charge of the region, who, it appears, have decided to adopt the cumbersome and scarcely accurate title of British Central Africa.

M MIZON's second expedition to Adamawa has been stopped on the Benué by the breakdown of his steamers, and the sudden falling of the water, he being left without means of progress about two-thirds of the way between Lukoja and Yola.

THE French flag has been formally hoisted on the little islands of St Paul and New Amsterdam in the South Indian Ocean, midway between the Cape of Good Hope and Australia. St Paul is an interesting instance of a volcanic island, the extinct crater of which forms a wide sheltered harbour communicating with the sea by means of a single narrow channel. It was one of the French stations for observing the transit of Venus in 1874. French fishermen from Reunion had practically taken possession of the islands in the early part of the century, but the fishing-grounds have long been abandoned.

MR B V DARRISHIRE, M A (Oxon), has been appointed Cartographer to the Royal Geographical Society. He has had the advantage of preliminary training in Germany, and under the Reader in Geography at Oxford.

### THE APPROACHING ECLIPSE OF THE SUN, APRIL 16, 1893<sup>1</sup>

I HAD the honour, two and a half years ago, of describing to you the total eclipse of the sun of December 22, 1889, which I had been to observe in the Salut Isles, French Guiana. In spite of very unfavourable atmospheric conditions I was then

<sup>1</sup> Address to the Astronomical Society of France, on November 2, 1892, by M. De la Baume Plevinél translated by A. Taylor.

able to take some photographs of the phenomena and to measure the actinic intensity of the corona. Two years previously I had been to Russia to observe the eclipse of August 18, 1887, but the bad weather prevented any observations. If these expeditions did not succeed as well as I had hoped, they were at least useful in showing me all the difficulties to be met with in such undertakings, and of convincing me that if one wishes to thoroughly avail one's self of the precious moments during which the eclipse lasts, it is necessary to gain a large experience of these phenomena by omitting no opportunity of observing them, and by making a speciality of these expeditions. Therefore, after the eclipse of 1889 I determined to go to observe the following eclipse, that of the 16th of next April.

This time the phenomenon is visible under particularly favourable conditions. On the African coast to the south of Dakar, where the expedition sent by the Bureau des Longitudes will observe, and where I also propose to instal myself, the duration of totality is four minutes thirteen seconds. Moreover, a very important consideration is that we are certain of fine weather. At a time when expeditions are being organised in every country in view of this astronomical event, I think it will be useful to draw your attention to the chief questions which should be the object of astronomical study during the next eclipse.

You are aware that the passing of the moon before the sun has the inestimable advantage of allowing us to see the circumsolar regions which, under ordinary circumstances, because of their faint light are lost in the general illumination of our atmosphere. The regions thus revealed consist of a layer in immediate contact with the sun, the chromosphere, in which are the rosy flames which form the protuberances, and a more or less extensive luminous aureole, the corona. But since the celebrated eclipse of 1868, which marks an epoch in the history of solar physics, we are able, thanks to the great discovery of Messrs Janssen and Lockyer, to study the protuberances at any time, and consequently it is only to the corona that the attention of astronomers turns during total eclipses.

An invariable part of the day's programme is the study of the structure of the corona, and the luminous intensity of its various parts. We need to have recourse to photography for trustworthy evidence as to this, for photography alone can give a faithful representation of the phenomena, even the best drawings always leave much to be desired. Indeed, it is impossible in the space of a few minutes to exactly represent a nebulous mass as complicated as the corona, and without any definite outlines. We can judge of the difficulty presented by the drawing of the corona, by remembering that even the most skilful draughtsmen have never yet been able to give us similar drawings of the great Orion nebula, although this may be studied at leisure. The brilliancy of the corona varies in intensity so much from one eclipse to another, that it is difficult to determine beforehand the length of exposure needed with given apparatus to obtain as satisfactory a representation of the phenomenon as possible. Moreover, the different parts of the corona differ in brilliancy, so that when the photographic action is sufficient to give a good image of the middle part, the lower portions which form the interior corona are over-exposed, while the extreme limits of the aureole are not reproduced. To satisfy all the conditions it is necessary to take several photographs with different exposures.

To advantageously discuss the results obtained it is very important that astronomers should place upon each plate a uniform scale to measure the intensity of the photographic action upon it. This intensity is equal to the product of three factors, the effectiveness of the object glass, the length of exposure, and the sensitiveness of the plate. If we indicate the useful diameter of the object glass by  $a$  and the focus by  $f$ , the effectiveness, defined by the international congress of photography, is

$100 \frac{a^2}{f^2}$ . If we take plates of gelatinobromide of silver of

normal sensitiveness as our unit, and let  $t$  be the length of exposure in seconds, we have the following formula to express

the photographic action:  $100 \frac{a^2 t}{f^2}$ . In working with wet

collodion plates it is necessary to multiply this expression by  $f^2$ , and with plates of dry collodion it must be multiplied by  $rt^2$ . The first photographs of the corona, taken with wet collodion, from 1868 to 1878, were obtained with a photographic action not greater than 2. Later, thanks to rapid plates, much greater action could be obtained. Thus in 1883 a photograph

obtained by M. Janssen had received a photographic action equal to 918. On the negative thus obtained, the corona extended to between 30' and 40' from the limb of the moon, but on the other hand, details of the parts near the sun were completely wanting.

We might ask whether by still further increasing the photographic action we should also extend the limits of the corona? Certainly not! For if the photographic action is too intense, the faint contrast between the extreme parts of the corona and the more or less illuminated sky is no longer appreciable on the negative. We know, indeed, that if we wish to produce the maximum contrast between two half tones we must only use just enough light for the faintest of the half-tones to give a perceptible image. In America, Mr. Burnham has been engaged in determining the maximum length of exposure necessary to obtain the best representation of the corona, and he has made experiments on this subject by photographing the moon and white clouds on a faintly lighted sky.

In 1889, at the Salut Isles, I used five instruments, giving photographic actions varying from 185 to 13, but, doubtless on account of the peculiarly intense illumination of the atmosphere due to the short duration of totality, and the great abundance of water vapour in the atmosphere, the most satisfactory negative was that corresponding to a photographic action of 30. It is very probable that an equally good result might have been obtained with much less photographic action. Mr. Barnard, to whom we owe the best photographs of the eclipse of January 1, 1889, worked with a photographic action equal to 0.58. This result proves that with the sensitive plates now in use it should be possible to obtain good images of the corona on a large scale by using secondary magnifiers to increase the size of the image given by the object glass. In any case we can employ object glasses of two or three metres focal length, which would give images sufficiently large to show all the details of the corona without having resort to enlargement of the plates. Nevertheless, in spite of the use of a long focus, the instrument must remain luminous enough for the time of exposure to be short. The displacements of the image on the plate, caused by the imperfect adjustment of the equatorial mounting, or by an irregularity in the clockwork movement, or by the movement of the sun in declination are thus rendered inappreciable.

The photographs, when obtained, should be examined from the following different points of view. First of all we wish to find if the corona, which will be observed in the month of April, 1893, at a period of great solar activity, and at an epoch when the south pole of the sun is projected on the visible part of its disc, resembles, as we have every reason to think it does, the corona of 1883, which was studied under the same conditions. A great resemblance between the forms of the corona in 1889 and 1878, at the periods of minimum sun-spots, has already been noted, and if it can be established that the corona, seen under similar conditions, presents the same appearance, it will be proved that the diversity of appearance hitherto noticed depends solely upon the state of agitation of the solar surface, and the position of the observer with respect to the solar equator.

If the corona should present an axis of symmetry it must be ascertained whether the poles of this axis coincide with the poles of the axis of rotation of the sun, or if, as is more usually the case, the poles of the corona are inclined at some degrees from the poles of the sun, thus resembling the position of the magnetic poles of the earth with regard to its geographical poles. If the corona shares in the movement of rotation of the sun, it must be the same with its axis of symmetry, and therefore if we once observe the northern pole of the corona to the east of the northern pole of the sun, we ought to find it after an uneven number of half-revolutions, of the sun to the west of the north pole of the sun. To ascertain if this is so or not, it is of the greatest importance to know exactly the orientation of the images upon the photographic plates. The most exact and simple method to orient the images is to place the photographic apparatus in the position which it occupied at the moment of the phenomena, and, in the night, to photograph the trails which the stars leave in passing across the field of the lens.

If the photographs should show the structure of the corona clearly, we shall be able to study the form of those luminous rays which we notice at the poles of the sun, and of those curvilinear structures which seem to extend from the middle latitudes of the sun. The study of the curvature of these structures will be very useful in verifying the exactness of one of the most favoured theories of the corona, which explains the phenomena

by supposing that matter is thrown out by the sun normally at its surface, and that its projection is turned on one side by the rotation of the sun. Mr Schaeberle, of the Lick Observatory, has mathematically studied this theory, and on applying it to eclipses already observed, has been able to report that the curvature of the structures has always conformed with the theory.

We must also examine the photographs taken with the longest exposure, to determine whether the dark parts which sometimes separate the luminous structures, and which we can trace to the base of the corona, are entirely destitute of light. The existence of these *rifts*, as the English call them, is difficult to explain, if we suppose that the coronal atmosphere entirely surrounds the sun, for in that case we should always see, projected on the plane perpendicular to the line of sight, the coronal matter all round the sun. According to Prof Hastings, the presence of these rifts is a confirmation of his theory which ascribes the corona to diffraction, and not to the existence of a material mass.

In the aspect of the corona quickly modified, or are the changes which we notice from one eclipse to another effected slowly? Hitherto we have never proved the difference between the photographs of the same eclipse taken at several hours' interval, and at stations very distant from each other. The English astronomers thought of testing this question in December, 1889, and the two English expeditions sent, one to the Salut Isles, and the other to the west coast of Africa, were furnished with photographic outfits as identical as possible, in order to obtain, at an interval of two and a half hours, comparable negatives of the corona. Unfortunately the complete failure of the expedition on the African coast did not permit the carrying out of this programme, otherwise it is very probable they would have proved no sensible difference between the negatives at the two stations, for photographs show that the corona of December 22, 1889, was almost identical with that of January 1 of the same year. We may say, then, that during the year 1889, a year of quietude on the solar surface, the appearance of the corona did not appreciably change.

However, the experiment attempted by the English expeditions needs to be repeated, if not to study the internal movements of the corona, to obtain identical photographs at two different angles, which would enable us, with the aid of the stereoscope, to judge of the *relief* of the corona.

Photographs of a total eclipse will not only inform us as to the structure of the corona, but will permit us to measure its actinic brightness. We can estimate the relative intensity of different parts of the corona by superposing several photographs, made on the same scale, but obtained with very different photographic actions. The outlines of each image would give lines of equal actinic intensity of the corona. The absolute intensity may be measured by comparing the opacity of the image on the plate with the opacities produced on the same plate from a source of standard light. For this purpose the plates destined for photography are previously exposed on their borders to a standard light for varying periods of time. When these plates are developed, a scale of tones which allows a comparison of opacities is obtained at the same time as the image of the phenomena.

The spectroscopic examination of the corona confronts us with still more complex and more interesting problems. When we keep the slit of the spectroscope on the crescent of the sun, which narrows more and more in proportion as the moon advances, the spectrum darkens and the dark lines become less and less apparent, then all at once the field of sight is covered with an infinite number of bright lines, which seem to be substituted for each dark line of the Fraunhofer spectrum. This phenomenon only lasts two or three seconds. Such is the remarkable observation made by Prof Young in 1870. In the preceding year he had tried to prove this transformation of dark into bright lines, but failed because he had arranged the slit of his spectroscope as a radius to the sun, which gave the bright lines too little length to be perceptible. With a tangential slit, however, the lines were long enough to be easily recognised.

Prof. Young's observations revealed to us the existence round the sun of a layer of incandescent vapours, of relatively low temperature, which, conformably to Kirchhoff's theory, produces by their absorbing power reversal of the lines of the solar spectrum. It is very probable that the vapours to which the reversal is due are not all situated in the atmosphere which Prof. Young has revealed to us, and which has a thickness of

only 1000 kilometres. If it were so, absorption must be infinitely more intense at the edge of the sun than it is at the centre. Nevertheless, the borders of the sun show no trace of this abnormal absorption. The observations of M. Janssen in 1867 showed this, and it is also proved by photographs of the spectrum of the sun which I took at the annular eclipse of 1890 at Canoe in the island of Crete.

It is probable that the reversal of lines is produced in a series of layers whose total thickness is great enough to make the difference of absorption between the centre and limb of the sun inappreciable. According to Prof. Lockyer the sun should be surrounded by concentric layers of vapours arranged in order of density, which, according to his own expression, envelope the sun like "the leaves of an onion." Prof. Young's layer of vapours would comprehend only some of these layers. This hypothesis seems confirmed by the observation made by M. Trépiéd in 1882, although he saw "a veritable rain of bright lines in the spectrum," he proved that the coincidence of the bright and dark lines was not complete.

Prof. Lockyer's theory involves also, as another consequence, the unequal length and width of these bright lines, indeed, the layer nearest to the sun should give short lines corresponding to the thickness of this layer, and as the temperature here must be very high the lines should be rather wide. The following layer being seen by projection, and having a thickness equal to the two layers, should give lines twice as long, moreover, this second layer being cooler than the preceding the lines should be narrower. The same reasoning applies to the succeeding layers, so that we ought to find, soon after the beginning of the total eclipse, short and wide lines, then long and narrow ones. The observations of 1882 confirmed these predictions, and English astronomers wished to repeat the experiment in 1886. Unfortunately the observations of Father Perry and Mr. Turner were made under conditions too unfavourable for us to draw any certain conclusion from them. To fully elucidate the question it is necessary to obtain instantaneous photographs of these bright lines. The experiment was indeed attempted by English observers in 1883, but they seem to have obtained no result. Prof. Lockyer proposes during the approaching eclipse to photograph these lines as well as the bright lines of the corona. He intends to use not only an analytic spectroscope, but a prismatic object glass. This apparatus will give the monochromatic images of the corona, that is to say, the kind of rings corresponding to each elementary radiation emitted by the coronal light.

When we turn the spectroscope towards the corona itself we observe a continuous spectrum, crossed by a bright green line which does not belong to any known element. This line, near the line E, corresponds to the division 1474 of Kirchhoff's scale, and was at first believed to coincide exactly with a line of iron, but in 1876 Prof. Young was able to separate the line 1474 with powerful dispersion, and proved that one of its two components belongs to iron while the other belongs to the coronal matter. This line 1474 has been shown in every total eclipse, but its intensity has been very variable and seems always to have followed the fluctuations of solar activity. Thus in 1878, a period of maximum spots, the green line was so faintly visible that it escaped all observers except two. On the other hand, in 1882, when the solar activity was almost at its maximum, the green line was visible to within 40' from the limb. However, we must remember that these estimations made by different observers, observing with very dissimilar instruments, are scarcely comparable, and trustworthy evidence can only be obtained from photographs of the spectrum of the corona. The new plates sensitive to the green will no doubt allow the line 1474 to be photographed in the approaching eclipse.

It would be interesting to know whether the intensity of the green line varies with the brilliancy of the different parts of the corona, whether it is completely wanting in the rifts, whether it extends further than the visible corona, whether it has the same width in its whole extent, &c. These observations can only be made by associating with the spectroscope a telescope serving as a finder, in which cross wires have been arranged to indicate at each moment towards what part of the corona the slit is directed. The spectrum is observed with one eye while with the other the corona is examined. This is the arrangement which M. Janssen has always adopted in his spectrum observations of the corona.

If the terrestrial atmosphere is loaded with water vapour, we must expect a general diffusion of the coronal light, and this is

doubtless the reason that on some occasions, as in 1870, the green line is seen beyond the corona—even upon the lunar disc.

Prof Hastings, in 1883, examined simultaneously with a special arrangement the spectra of east and west portions of the corona, and proved, conformably to the theory that he propounds, that the green line varied in length during the duration of the eclipse, and that it always extended furthest on the most illuminated side of the edge of the moon. Mr. Keeler repeated the experiment in 1889, and also noted that the length of the green line depends upon the position of the sun with respect to the moon. The question would be worth studying further.

The green line is not the only bright line in the spectrum of the corona, the hydrogen lines have also been discovered in it, but these never extend further than about  $10'$  from the sun's limb. Other bright lines in the red and in the violet were observed by M. Tachini and by Thallon in 1882. It was in 1882 also that Prof. Schuster obtained the first photograph of the coronal spectrum upon which some thirty bright lines may be counted.

In addition to the incandescent solid or liquid matter producing the spectrum of the corona, and the incandescent gases, which give rise to bright lines, there must also be in the circum-solar regions matter reflecting the light of the photosphere, as our own atmosphere does. This is proved by the polarisation of the light of the corona, and by the presence in its spectrum of the dark lines of the Fraunhofer spectrum. We owe the discovery of these dark lines to M. Janssen. In 1871 he observed only the lines D and  $\delta$ , but, since, in 1883, he has recognised some hundred dark lines, thus showing that the complete Fraunhofer spectrum is found in the coronal spectrum. These dark lines are necessarily very faint, for they are drowned in the continuous spectrum. As a rule the line D is most conspicuous, although, according to Prof. Hastings, if a faint solar spectrum is projected on to the continuous spectrum of a gas flame, it is not the line D, but rather the group  $\delta$ , which is by far the most apparent. Prof. Hastings concludes from this experiment that the continuous spectrum of the corona is richer in green than in orange radiation, since it causes the group  $\delta$  to disappear before the line D.

In conclusion I must quote a remarkable observation made by Prof. Tachini in 1883, which, should it be confirmed, would suggest a very fascinating theory of the corona. Upon examining the spectrum of one of the sheaves (panaches) of the corona with a considerable dispersion and a wide slit, Prof. Tachini thought he recognised two or three bright bands characteristic of the hydrocarbons, which are always present in the spectra of comets. Father Perry in 1886 proposed to verify the observation of Tachini, but unfortunately could not re-observe the bands in question. Certainly he used a spectroscope with slightly illuminated cross wires, and when the period of great solar activity had already passed. It would be well in future eclipses to devote some seconds to the search for these bands, for, if the presence of carbon were recognised in the coronal atmosphere, it would be a new proof of the analogy which exists between the corona and cometary masses. Like comets the corona seems formed of matter subject to a repulsive force on the part of the sun, indeed it is probable that solar gravity does not act upon the corona, for unless this were so, the lower parts, having to support the weight of the upper, would be much more dense than the latter. It would thus result that the lines of the coronal spectrum, the line 1474 for instance, would be wider at their bases than at their upper extremities, but nothing of the kind has hitherto been observed. Moreover, so that the corona may be visible at  $30'$  or  $40'$  from the sun, the coronal matter must necessarily not be too rare in these extreme regions; but even in ascribing an extremely low density to this, we should find upon allowing for solar gravity that the pressure near the sun would have a considerable value, although it is proved that the pressure at the base of the corona does not exceed some millimetres of mercury.

It is also sought to prove the slight density of the middle corona by the fact that it has never offered any resistance to comets, which, on several occasions, have passed through it, but as comets themselves experience no appreciable resistance when they encounter a body it is impossible to tell whether the absence of resistance is due to the comets or to the corona.

The repulsive force which expels the coronal matter from the sun would act in the same manner as electrical force; indeed Prof. Bigelow has noticed that the arrangement of plumes and

sheaves round the solar disc, and the incurvilinear forms exactly recall the lines of force of an electric field. Let us complete the parallel between comets and the corona by noting that the tails of comets sometimes assume the curvilinear form found in the sheaves of the corona. The dark parts which divide the tails of comets have also their analogues in the rifts of the corona. To push the comparison still further, it would be very interesting to be able to prove that the corona, like cometary masses, is transparent, and that bright stars can be seen through it. Unfortunately it will be impossible to attempt this experiment at the time of the next eclipse.

An exact photometric study of the solar surface would perhaps detect the transparency of the corona, indeed if we suppose that the corona presents a certain opacity the parts of the photosphere on which the large sheaves are projected must be less luminous than the parts covered by the polar rays.

If the corona is not subject to solar gravity it is scarcely probable that it shares the movement of rotation of the sun, however, it would be useful to try in the coming eclipse to study the question by the spectroscopic method, as M. Trouvelot wished to do in 1883. It would be desirable to conduct all spectroscopic observations of the corona by means of photography. The instruments which must be used for this purpose should be very luminous (*i.e.* give bright images), for there is little light available, and the exposures are necessarily short. In studying the effectiveness of a spectroscope in the case of an object presenting a large apparent diameter, like the corona, it is seen that the intensity of the spectrum depends entirely upon the width of the slit, and the effectiveness of the object glass which forms the image of the spectrum. As to the collimator and the condenser their dimensions are of no importance, provided that the collimator can well receive all the light of the condenser. As the object glass which forms the image of the spectrum must have an image long enough to give sufficient length to the spectrum, one is led, in order to obtain great effectiveness, to give this object glass a large aperture, and consequently to use a prism of large size.

The visibility of the bright lines depending not only on their brightness, but also on their width, a wide slit must be employed to obtain a good image of these lines, on the other hand, a narrow slit will give a spectrum of great purity, and will show the dark lines. The employment of two different spectroscopes is then plainly indicated.

It remains for us to speak of the photometric measuring of the corona by optical photometers. Hunsen's photometer has already been used for this purpose, but I think that we must henceforth turn to photography to obtain exact results. The question should not be neglected, for it is certain that the brilliancy of the corona varies considerably from one eclipse to another. Thus Prof. Lockyer estimates that in 1878, at a period of quiescence on the surface of the sun, the corona was ten times less brilliant than in 1871.

Let us end by pointing to the polariscope observations which hitherto have been far from giving concordant results as to the proportion of polarised light in the various parts of the corona. Here also there are new inquiries to be made.

Such, gentlemen, are the different problems suggested by the study of the solar corona. We will hope that the next eclipse will largely contribute to their solution.

#### MEMORIAL OF SIR RICHARD OWEN

A MEETING was held at the rooms of the Royal Society, on Saturday, to make preparations for the provision of a suitable memorial of the late Sir Richard Owen. The Prince of Wales took the chair, and was supported by the Duke of Teck, the President, the Treasurer, and the Secretary of the Royal Society, Lord Kelvin, Sir John Evans, and Professor Michael Foster, the President of the British Association, Sir A. Geikie; the President of the Royal College of Physicians, Sir A. Clark; the President of the Royal College of Surgeons, Mr. T. Bryant, the President of the Royal Academy Sir F. Leighton; the Bishop of Rochester, the Dean of Westminster, Lord Playfair, Prof. Huxley, Sir H. Roscoe, M.P., Sir F. Abel, Sir F. Bramwell, Sir G. Stokes, Sir H. Acland, Sir Joseph Lister, Mr. Ericson, Dr. Priestley, Dr. Gunther, Dr. H. Woodward, Dr. Maunde Thompson, Sir W. H. Flower, Sir Erasmus Ommanney, Sir James Paget, Sir Henry Thompson, Sir Spencer Wells, Sir Edwin Saunders, Sir John Fowler,

Dr E A Bond, Dr P L. Sclater, Mr Carruthers, and Mr W. P. Sladen. There were also present, among others, Sir G M Humphry, Mr Holman Hunt, Mr Ernest Hart, Dr Michael (President of the Royal Microscopical Society), Prof. R Meldola, Mr O Salvin, and Prof T Wiltshire.

The Prince of Wales, in opening the proceedings, said,—I have the great privilege conferred upon me of being asked to take the chair to-day, upon this very special occasion. We are assembled together for the purpose of paying a mark and tribute of respect and appreciation to the memory of a great man of science who has lately passed away from us. The name of Sir Richard Owen must always go down to posterity as that of a great man—one who was eminent in the sciences of anatomy, zoology, and palæontology. Perhaps I may be allowed to say a word of my own personal knowledge of him. It is now thirty-five years since I had the advantage of knowing him. When I lived as a boy at the White Lodge, Richmond Park, now occupied by my illustrious relative on my right (the Duke of Teck), I had opportunities of visiting him and knowing him. His geniality and his charm of manner to all those who knew him have, I am sure, left a deep and lasting impression. Whether he was explaining to you the mysteries of some old fossil bone that had been given him, or whether he was telling one of his vivid ghost stories, one felt that one was under the charm of his presence. His method of teaching, as you all know, was earnest and clear in every respect, and it even derived a measure of force from a certain hesitation in his manner. His great repute was gained as a zoologist, and in the study, not only of living animals, but of those long extinct, and following the same large range of work as Cuvier, to whom, in the history of science, he may be regarded as a successor. One of the great works and interests of his life was the formation of the Natural History Museum, which is now safely established in South Kensington under the able guidance of our friend Sir William Flower. It may be within your recollection what great difficulties Sir Richard Owen encountered when he was first appointed Superintendent of the Department of Natural History at the British Museum in 1856. He himself saw in getting that appointment that it was quite impossible that these large collections could be adequately seen unless they were removed to some other sphere. In 1862 a Bill was brought in by Mr Gladstone, who took the greatest interest in the matter, while it was vigorously opposed, strange to say, by no less great a man than Mr Disraeli. The Bill was lost, though it was eventually, ten years later, carried, and now we have that fine building that we all know and deeply appreciate. I may also mention that he took the greatest interest with regard to the colonies, and in trying to obtain from them specimens that would be worthily represented in the Natural History Museum. In sanitary matters also he was not behindhand, as was shown by his long intimacy with that distinguished man, Sir Edwin Chadwick. There are several resolutions to be proposed, and you will hear far better and more eloquent remarks from the distinguished gentlemen who will move and second them. That is the reason why on this occasion I shall not trouble you with more remarks. Allow me only to repeat the assurance of the deep interest I take in this movement for a suitable memorial to the memory of this great man, and how deeply I appreciate having been asked to take the chair on this interesting and important occasion.

Lord Kelvin moved —“That it is desirable that the eminent services of the late Sir Richard Owen in the advancement of the knowledge of the sciences of anatomy, zoology, and palæontology should be commemorated by some suitable memorial.” He said that, if there was no other reason but the part that Sir R. Owen took in the establishment of the Natural History Museum, and the success that ultimately attended his efforts, he deserved the gratitude of the nation. There was scarcely any branch of the whole of natural history that he had not touched and enriched with the results of his investigations. Three hundred and sixty papers, every one of them valuable, were to be found under his name in the Royal Society catalogue of scientific papers. From these contributions, however, he came back to the Natural History Museum, and he held that every subject of the Queen, in these islands or in the colonies, and every visitor to this country, must feel that he was benefited by the existence of that museum and by the splendid arrangement of its contents.

Prof. Huxley, in seconding the resolution, said that, if he mistook not, there were very few men living who had had occasion to follow the work of the remarkable man whose career

they had met to celebrate with more carefulness and attention than he had done. It was a career remarkable for its length, for the rapid rise to eminence, and the long retention of high position of the person who was the subject of it. It was more than forty years ago since he, as a young man, had occasion to look abroad upon the scientific world of London, in which he was then a complete novice, and to see whether, perhaps, in some small and insignificant corner of it room might be found for him. At that time there were four persons whose names stood out amongst the first in the galaxy of scientific men of this country. They were Sir John Herschel, Mr Faraday, Sir Charles Lyell, and, last, though by no means least, the famous Hunterian Professor, Owen. If he looked abroad amongst the lights of biological science, with which he was principally concerned, there were Johannes Muller in Berlin, Milne Edwards in Paris, Von Baer in St Petersburg, but for quantity, general excellence, and variety of work there was no one who could be regarded as the superior of Owen. It was a common impression that Owen was the successor and continuator of Cuvier, and that was largely true. The memoirs on the pearly nautilus, on the marsupials, on the anthropoid apes were fully worthy of the author of the “*Mémoires sur les Mollusques*” or the “*Leçons d'Anatomie Comparée*,” while the “*Ossesmen fossiles*” had a full equivalent in the vast series of papers upon fossil remains, contained in the publications of the Royal, the Geological, and the Palæontographical Societies. But it was also to be remembered that, in another field, Owen was the successor and continuator of the school to which Cuvier was most vehemently opposed—that of St Hilaire and Oken. The remarkable contributions to morphology embodied in the works on the archetype of the vertebrate skeleton and on the nature of limbs were able developments of speculative views of another order than Cuvier's. Readers of Goethe would remember that he thought the news of the controversy between Cuvier and St. Hilaire far more interesting than that of the Revolution of July, which broke out about the same time. Whether that was a just estimate of the relative importance of things or not might be left an open question, but it was the peculiar irony of history to show us in so many quarrels that right and wrong were on both sides. And in this particular controversy it had turned out that the right lay neither with Cuvier nor with St. Hilaire, but partly with both and partly with a third party, which at that time hardly existed. Whatever might be the ultimate verdict of science in this particular matter, there could be no doubt that it was a distinct aid to progress to have one view of the case stated and illustrated with the unrivalled wealth of knowledge which Owen brought to bear upon it. If history confirmed, as he believed it would, the estimate of the broad features of Sir Richard Owen's work, which he had suggested, then it would justify them in endeavouring to preserve the memory of the great results achieved by his stupendous powers of work, his remarkable sagacity in interpretation, and his untiring striving towards the ideal which he entertained.

The resolution was then put and agreed to unanimously, as were also those which followed.

The Duke of Teck moved —“That the memorial shall consist primarily of a marble statue which shall be offered to the Trustees of the British Museum to be placed in the hall of the Natural History Museum.” His Royal Highness said,—There is no doubt, in my mind at least, that this would be the most appropriate place and the most appropriate form in which to erect the likeness of our admired friend. It is, so to say, his second home, the home of his later labours, and no better place could be found. Besides, I think it is a very nice idea that every one who enters the hall should see first of all the man to whom we owe this inheritance. Others have said so much about Sir Richard Owen that it is needless for me to go over the ground again. As all of us know so well, what he has been and what he has done will remain in the minds of all who survive him, and, therefore, I will only say that in my opinion the hall, which is a very fine interior, of the Natural History Museum should be the place where the memorial of this great man should be erected.

Sir William Flower, in seconding the resolution, said that having twice in his life succeeded Sir Richard Owen, he had had special opportunities of judging of his work, and he might, therefore, be expected to say something about the general character and extent of that work on the present occasion, but after what had been said in the introductory remarks of His Royal Highness, and the speech of Prof. Huxley, than whom no one

was more competent to give an opinion upon the scientific side of the question, there was no necessity for doing so. He could not refrain, however, from speaking upon one point. Among the various characteristics of Sir Richard Owen, one of the most remarkable was his untiring industry, which enabled him to produce an amount of work which was truly prodigious. It could hardly be expected that such a vast series of memoirs on so many diverse subjects, as that which he had given forth to the world during his long life, could all be equal in quality, or that the merits of some of them should not have been the occasion of controversy. He would only refer to one instance of this kind. As long ago as 1837, Sir R. Owen read a paper before the Society in whose rooms they were now assembled, which was published in the *Philosophical Transactions*, and in which certain remarkable characteristics were stated to exist in the brain of marsupial animals, widely distinguishing them from other members of the class to which they belong. The conclusions apparently established by this paper were generally accepted for nearly thirty years, but in 1865 another memoir was read before the same society, and also published in the *Philosophical Transactions*, in which a different view was taken both of the nature of the structural peculiarities and of their significance in classification. The views of the author of this second paper have generally found favour until within a few months since, when an independent investigation of the subject, carried on with all the improved methods of modern research, by Dr. J. Symington, has resulted in a declaration in favour of the accuracy of Owen's original description and conclusions. These observations may still require confirmation by others, but as he (Sir W. Flower) was the author of the second paper, he considered it only fitting that he should, at a meeting assembled to do honour to the memory of the great anatomist, from whom, on this point, he had differed so long, call attention to them. He thought this the best contribution he could make to the object for which they had gathered together.

Dr P. L. Slater suggested that, in addition, a memorial catalogue of the late professor's writings should be issued, with a portrait and biographical memoir.

Sir James Paget moved that a committee be formed to carry out the preceding resolutions. It would be impossible, he said, to have any better evidence that the resolutions just passed were right than the number and position of those who had offered to serve on the committee, for there was never a more representative list. Headed by the Prince of Wales, the Duke of Teck, the Archbishop of Canterbury, and the Lord Chancellor, it contained nearly 150 of the most prominent workers in all branches of science and many who were the best judges of the influence of science on the general well-being of the nation. He was the oldest person present who had worked with Sir R. Owen, and could remember him on entering St. Bartholomew's Hospital as a student in 1834. He could testify to the influence Owen had exercised in promoting the study of science by showing to all around him how keen his delight was in it, and how in itself alone it might be a sufficient reward. He resisted all temptations to leave science, though he might have been a very successful medical practitioner, and he was one of the first by whom the real reform of sanitary matters was begun in this country.

Sir J. Evans briefly seconded the motion.

Sir A. Clark moved—"That the following list of gentlemen constitute the executive committee. His Royal Highness the Prince of Wales (chairman), His Serene Highness the Duke of Teck, the President of the Royal Society, the President of the Royal College of Physicians, the President of the Royal College of Surgeons, the President of the Linnæan Society, the President of the Zoological Society (treasurer), Sir John Evans, Prof. Michael Foster, Dr. A. Günther, Prof. Huxley, Sir F. Leighton, Sir James Paget, Dr. P. L. Slater, Mr. W. Percy Sladen (secretary), Lord Walsingham, Mr. A. Waterhouse, R. A., and Mr. Henry Woodward." Sir Andrew remarked that this memorial movement reminded them that nations no more than individuals can live by bread alone. Material prosperity did not constitute the true abiding life of a nation; it was necessary that it should live by ideas, and the nation honoured those who, like Owen, communicated new ideas which spurred others to new courses of activity.

Mr. T. Bryant, in seconding the motion, said the College of Surgeons felt the loss that science had sustained in the death of him who unquestionably was the grand expounder of John Hunter and who, more than any one else, demonstrated the

value of the materials John Hunter left behind him. He did more than any one else to call the attention of the scientific world to the museum in Lincoln's Inn, and by additions to it to make it what it is. More than that, at a time when comparative anatomy and biological studies were little thought of, he called attention to the value of them, the necessity for them, and the pleasures they would yield. As a young man he attended Owen's lectures, and felt the full force of his quiet enthusiasm, which was altogether independent of the materials embodied in the lectures.

Lord Playfair, in supporting the motion, said that he was the last surviving member of the Health of Towns Commission of 1844, upon which he was brought into continual intercourse with Sir R. Owen, and therefore he knew how much Sir Richard had at heart the advancement of sanitary science. This interest in it he maintained throughout his whole career. He lived close to Sir Edwin Chadwick, and although no two men could be more unlike, they were most intimate friends, and were constantly discussing how to advance the health of the nation. When Sir Richard returned from his interesting expedition to Egypt he told the speaker that he had come back in an unforgetting spirit towards Moses, because though skilled in the learning of the Egyptians, and having derived his chief commandments from those of that ancient race, he missed one important one, "Thou shalt not pollute rivers." Owen, like Prof. Huxley, exercised great influence outside the domain of science. Prof. Huxley had benefited the education of the country, and Prof. Owen had considerable influence in improving the sanitary condition of the country.

Sir W. Flower read a first list of donations, headed with one of £25 by the Prince of Wales.

Sir Henry Acland moved, and Prof. Michael Foster seconded, a vote of thanks to his Royal Highness for consenting to become chairman of the committee, and for presiding on the present occasion.

The Prince of Wales, in responding, said,—I beg to return my warmest thanks to my kind and valued old friend, Sir Henry Acland, for the way he has proposed, to Mr. Michael Foster for the way in which he seconded, and to you all for the kind manner in which you have received this resolution. It has indeed been a labour of love to me to-day to preside on this very interesting occasion, and I think that it has seldom been my good fortune to listen to more interesting or eloquent addresses than those which have fallen from the lips of those eminent gentlemen who have spoken. Nobody will take a deeper interest in the carrying out of this memorial of our lamented friend Sir Richard Owen than myself, and most sincerely do I hope that the great work that is to adorn the Natural History Museum will be worthy of a great sculptor and of the great man that it represents.

## SCIENTIFIC SERIALS

*Bulletin de l'Académie Royale de Belgique*, Nos 9 and 10. *Classe des Sciences*.—On some new *Catigides* of the coast of Africa and the Azores Archipelago, by P. J. van Beneden.—On an optical atmospheric phenomenon observed in the Alps, by F. Folie (see Notes).—On a state of matter characterised by the mutual independence of the pressure and the specific volume, by P. de Heen. It is easily shown that the density of saturated vapour at the critical temperature is variable, and depends, at constant pressure, upon the proportion of liquid enclosed in the tube. Experiments were made in order to decide whether this independence of pressure and volume was shown also at other temperatures. The liquid chosen was ether, and the volume of liquid and vapour contained in a sealed tube was read by means of a cathetometer. A series of results showed that during condensation by pressure the density of unsaturated vapour was greater than that of saturated vapour, or that the specific volume increased with the pressure. This is an experimental verification of Prof. James Thomson's pseudo-gaseous state of matter.—On the most complete reduction of invariant functions, by Jacques Deruyts.—Ex-meridian observations made at the Royal Observatory of Belgium from March to October, 1892, by L. Niesten and E. Stuyvaert.—On a new fluorine-derivative of carbon, by Frédéric Swarts. This is a liquid, of the formula  $\text{CCl}_2\text{F}$ , boiling at  $24^\circ 7$ , insoluble in water, and unaffected by sulphuric and nitric acids. Its density is 1.4944, an alcoholic solution of

potash destroys it gradually, forming potassium chloride, fluoride, and carbonate. It was obtained by treating carbon tetrachloride with a mixture of antimony trifluoride and bromine in equal molecular proportions. It is notable that the bromofluoride produced by the mixture acts not as a bromising but a fluorising agent. — On a simplification of some of Te-la's experiments, by H. Schoentjes. Like some recent workers in England, Prof. Schoentjes has found that most of the experiments can be produced, although with lesser intensity, without the bobbin immersed in oil, the discharge exciter, and the condenser, simply by the first Rhumkorff coil, whose dimensions need not exceed  $7 \times 17$  cm. — On a process of sterilisation of albumin solutions at  $100^\circ\text{C}$ , by Emile Marchal. Albumin can be easily sterilised at  $100^\circ\text{C}$ , without coagulation, by first adding 0.05 gr. per litre of borax, or 0.005 of ferrous sulphate in a 2 to 5 per cent solution, or 4 to 5 gr. nitrate of urea per litre of 10 per cent solution. The "incoagulable albumin" thus obtained is perfectly suitable for cultivations.

## SOCIETIES AND ACADEMIES

LONDON

Royal Society, November 24, 1892 — "Memoir on the Theory of the Compositions of Numbers," by P. A. MacMahon, Major R. A., F. R. S.

In the theory of the partitions of numbers the order of occurrence of the parts is immaterial. Compositions of numbers are merely partitions in which the order of the parts is essential. In the nomenclature I have followed H. J. S. Smith and J. W. L. Glaisher. What are called "unipartite" numbers are such as may be taken to enumerate undistinguished objects. "Multipartite" numbers enumerate objects which are distinguished from one another to any given extent, and the objects are appropriately enumerated by an ordered assemblage

of integers, each integer being a unipartite number which specifies the number of objects of a particular kind; and such assemblage constitutes a multipartite number. The 1st Section treats of the compositions of unipartite numbers both analytically and graphically. The subject is of great simplicity, and is only given as a suitable introduction to the more difficult theory, connected with multipartite numbers, which is developed in the succeeding sections.

The investigation arose in an interesting manner. In the theory of the partitions of integers, certain partitions came under view which may be defined as possessing the property of involving a partition of every lower integer in a unique manner. These have been termed "perfect partitions," and it was curious that their enumeration proved to be identical with that of certain expressions which were obviously "compositions" of multipartite numbers.

The generating function which enumerates the composition has the equivalent forms—

$$\begin{aligned} & h_1 + h_2 + h_3 + \dots \\ & 1 - h_1 - h_2 - h_3 - \dots \\ & \frac{a_1 - a_2 + a_3 - \dots}{1 - 2(a_1 - a_2 + a_3 - \dots)}, \end{aligned}$$

where  $h_s$ ,  $a_s$  represent respectively the sum of the homogeneous products of order  $s$  and the sum of the products  $s$  together of quantities

$$a_1, a_2, a_3, \dots, a_n,$$

and the number of compositions of the multipartite

$$p_1 p_2 \dots p_n$$

is the coefficient of  $a_1^{p_1} a_2^{p_2} \dots a_n^{p_n}$  in the development according to ascending powers.

It is established that

$$\frac{1}{1 - s_1(2a_1 + a_2 + \dots + a_n)} \{1 - s_2(2a_1 + 2a_2 + \dots + a_n)\} \{1 - s_n(2a_1 + 2a_2 + \dots + 2a_n)\}$$

is also a generating function which enumerates the compositions, the coefficient of

$$s_1^{p_1} s_2^{p_2} \dots s_n^{p_n} a_1^{p_1} a_2^{p_2} \dots a_n^{p_n}$$

being the number of compositions possessed by the multipartite

$$p_1 p_2 \dots p_n$$

The previous generating function may, by the addition of the fraction  $\frac{1}{2}$  and the substitution of  $s_1 a_1$ ,  $s_2 a_2$ , &c., for  $a_1$ ,  $a_2$ , &c., be thrown into the form

$$\frac{1}{1 - 2(\sum s_1 a_1 - \sum s_1 s_2 a_1 a_2 + \dots + (-)^{n+1} s_1 s_2 \dots s_n a_1 a_2 \dots a_n)}$$

and hence these two fractions, in regard to the terms in their expansions which are products of powers of  $s_1 a_1$ ,  $s_2 a_2$ , ...,  $s_n a_n$ , must be identical. This fact is proved by means of the identity—

$$\frac{1}{1 - s_1(2a_1 + a_2 + \dots + a_n)} \{1 - s_2(2a_1 + 2a_2 + \dots + a_n)\} \{1 - s_n(2a_1 + 2a_2 + \dots + 2a_n)\} = \frac{1}{1 - 2(\sum s_1 a_1 - \sum s_1 s_2 a_1 a_2 + \dots + (-)^{n+1} s_1 s_2 \dots s_n a_1 a_2 \dots a_n)}$$

multiplied by

$$1 + \sum \frac{2(A_{k1} + a_{k1})}{(1 - S_{k1})} \frac{(A_{kt} + a_{kt}) - (A_{k1} + 2a_{k1})}{(1 - S_{kt})} \frac{(A_{kt} + 2a_{kt})}{S_{k1} S_{k2} \dots S_{kn}},$$

where

$$S_k = s_k(2a_1 + \dots + 2a_k + a_{k+1} + \dots + a_n) = s_k(A_k + 2a_k),$$

and the summation is in regard to every selection of  $t$  integers from the series

$$1, 2, 3, \dots, n,$$

and  $t$  takes all values from 1 to  $n - 1$ .

This remarkable theorem leads to a crowd of results which are interesting in the theory of numbers.

The geometrical method of "trees" finds a place, and, lastly, there is the fundamental algebraic identity—

$$\begin{aligned} & \frac{1}{k} \frac{1 - s_1(ka_1 + a_2 + \dots + a_n)}{1 - k\sum s_1 a_1 + k(k-1)\sum s_1 s_2 a_1 a_2 - \dots + (-)^{n+1} k(k-1)^{n-1} s_1 s_2 \dots s_n a_1 a_2 \dots a_n} \\ & = \frac{1}{k} \frac{1}{1 - k\sum s_1 a_1 + k(k-1)\sum s_1 s_2 a_1 a_2 - \dots + (-)^{n+1} k(k-1)^{n-1} s_1 s_2 \dots s_n a_1 a_2 \dots a_n} \end{aligned}$$

multiplied by

$$1 + \sum \frac{k(A_{k1} + a_{k1})}{(k-1)(1 - S_{k1})} \frac{(A_{kt} + a_{kt}) - (A_{k1} + ka_{k1})}{(1 - S_{kt})} \frac{(A_{kt} + ka_{kt})}{S_{k1} S_{k2} \dots S_{kn}},$$

which reduces to that formerly obtained when  $k$  is given the special value 2.

**Chemical Society, December 13**—Mr. W Crookes, Vice-President, in the chair—The Stas Memorial Lecture, by J W Mallet, was read (see this vol p. 248)

December 15.—Dr. W J Russell, Vice-President, in the chair.—The following papers were read.—The identity of caffeine and theine and the interactions of caffeine and auric chloride, by W R. Dunstan and W F J Shephard. Various physiologists have concluded that differences exist between theine from tea and caffeine from coffee, the authors have compared the products from the two sources, and consider that their identity is beyond question. The differences in physiological action observed by Mays, Bruntton, and Cash can only mean that the alkaloids employed were either impure or administered under non comparable conditions. On heating an aqueous solution of caffeine aurichloride, a yellow precipitate of aurichloro-caffeine  $C_8H_8(AuCl_2)N_4O_3$  separates, the production of this substance is better explained by Medicus' formula for caffeine than by that of E Fischer.—Studies on isomeric change, 11. Orthoxylenesulphonic acids, by G T Moody. 1 2 3 orthoxylenesulphonic acid, when heated at 115–120° in a current of dry air, undergoes quantitative conversion into the isomeric 1 2 4 sulphonic acid. The former acid is prepared by sulphonating dibromorthoxylene and reducing the resulting dibromorthoxylene-sulphonic acid with zinc dust and sodium hydroxide. A number of derivatives are described.—Studies on isomeric change, 11. Phenetolsulphonic acids,  $C_6H_4(OEt)SO_3H$ , by G T Moody. Bromophenetolsulphonic acid, prepared by ethylating parabromophenol and sulphonating the bromophenetol so obtained, is readily reduced by zinc dust and sodium hydroxide with formation of orthophenetolsulphonic acid. The latter is completely converted into the isomeric parasulphonic acid on heating for several hours at 100°. Lagat's observations, contradicting the author's previous results, are shown to be erroneous.—Formation and nitration of phenyldiazomide, by W A Tilden and J H Millar. Phenyldiazomide,  $N_3Ph$ , is readily obtained by the interaction of nitrosyl chloride and phenylhydrazine in glacial acetic acid solution, on nitration it yields about two-thirds of its weight of the paranitro-derivative (m.p. 74°). Nitrophenyldiazomide is a convenient source from which to prepare diazomide.—The production of naphthalene derivatives from dehydracetic acid, by J N Collie. The author concludes that the yellow substance which he has previously obtained by the condensation of diacetylacetone (see this vol p 238) is probably formed in accordance with the following equation—

This substance gives a diacetyl derivative which on distillation with zinc dust yields a trimethylnaphthalene. The condensation product closely resembles the acetoneaphthols prepared by Wilt and Erdmann—A new synthesis of hydrindone, by F. S. Kipping. Contrary to the statement of Hughes, hydrindone may be easily prepared in large quantities by the action of aluminium chloride on phenylpropionic chloride, 50–60 per cent of the theoretical yield is obtained, the reaction being represented by the following equation:  $\text{Ph} \cdot \text{CH}_2 \cdot \text{CH}_2 \cdot \text{COCl} = \text{Ph} \left\langle \begin{array}{c} \text{CH}_2 \\ \text{CO} \end{array} \right\rangle \text{CH}_2 + \text{HCl}$ . The ketone prepared in this way is identical with that obtained from other sources by several chemists, its hydrazone, hydroxime and a nitro-derivative are described. On heating hydrindone with moderately concentrated sulphuric acid a condensation product,  $\text{C}_{18}\text{H}_{14}\text{O}$ , is obtained, it forms yellowish plates melting at  $141.5\text{--}142.5^\circ$ . Phosphoric anhydride converts hydrindone into a yellow crystalline substance, which is apparently identical with the hydrocarbon of the empirical com-

position  $C_3H_5$ , which the author has previously obtained by the action of phosphoric anhydride on phenylpropionic chloride — The resolution of methoxysuccinic acid into its optically active components, by T Purdie and W Marshall — Synthetic methoxysuccinic acid can be resolved into its optically active constituents by crystallisation of the acid cinchonine salts, the salt of the dextro acid being less soluble in water than that of its lævo-isomeride. The separation effected in this way is, however, only partial, the metallic salts obtained after removal of the alkaloid being a mixture of the active and inactive compounds, by taking advantage of the fact that the inactive calcium or acid potassium salt is less soluble in water than its active isomeride, the optically active acids may be isolated. The active acids have a specific rotatory power of about  $33^\circ$  in 5–10 per cent aqueous solutions and melt at  $88-90^\circ$ , whilst the inactive acid melts at  $108^\circ$ . The rotation of the normal ammonium or potassium salt is of the same sign as that of the parent acid, the rotation of the calcium or barium salt is of opposite sign to that of the acid, but varies greatly with change of concentration. The rotation of the barium salt changes sign in very dilute solutions — Optically active ethoxysuccinic acid, by T Purdie and I W Walker. If fed with nutritive mineral salts the spores of *Penicillium glaucum* flourish in a solution of inactive hydrogen ammonium ethoxysuccinate and consume the lævogyrate acid, leaving the dextro-acid unaltered. On crystallising the cinchonidine salt of the inactive acid, a separation into the lævo- and dextro modifications may be effected, and the oppositely active acid ammonium salts prepared in this way resemble that obtained by means of *Penicillium glaucum*. Close parallelism exists between the methoxy- and ethoxy succinates, with respect to optical activity. — The formation of benzylidihydroxypyridine from benzylglutaconic acid, by S Ruhemann. Ethyl benzylglutaconate slowly dissolves at  $100^\circ$  in concentrated aqueous ammonia, yielding a solution, from which acids separate benzylidihydroxypyridine. This substance exhibits both basic and acid properties, and melts at  $184^\circ$ . — The action of nitrous acid on 1- $\alpha$ -amido-2- $\beta$  naphthol, a correction, by R Meldola. The author agrees with the statement of Grandmougin and Michel that  $\beta$  naphthaquinone results from the interaction of nitrous acid and 1- $\alpha$ -amido-2- $\beta$  naphthol. — Note on the action of phenylhydrazine on mono- and di-carboxylic acids at elevated temperatures, by W R Hodgkinson and A H. Coote. On distilling a mixture of phenylhydrazine and phenylacetic acid in equivalent proportion, benzene, aniline and a liquid of the composition  $C_{14}H_{15}O_2$  distil over, nitrogen and ammonia are also evolved. As has been previously shown, the hydrazone of the composition  $Ph \cdot CH_2 \cdot CO \cdot NH \cdot NH \cdot Ph$  is the first product of the reaction, on distilling this substance,  $NH \cdot NH$  is split off, and reduces the phenylhydrazine present to aniline and benzene. Somewhat similar reactions occur in the cases of orthotoluic, phenylpropionic, and succinic acids, and are now under investigation.

## SYDNEY

Royal Society of New South Wales, September 7, 1892.  
—Prof Warren, President, in the chair.—Paper read The effect which settlement in Australia has produced upon the indigenous vegetation, by A G Hamilton [Part I]

October 5.—Prof. Warren, President, in the chair.—The second part of paper on the effect which settlement in Australia has produced upon indigenous vegetation, by A. G. Hamilton, was read, after which the society's bronze medal and a cheque for £25 were presented to the author.

November 2.—Prof. Warren, President, in the chair.—Dr William Huggins, F.R.S., was elected an honorary member of the Society. The following papers were read.—Preliminary note on limestone occurring near Sydney, by H. G. Smith.—On a cyclonic storm near Narrabri, by H. C. Russell, F.R.S.—Some folk-songs and myths from Samos, translated by the Rev. G. Pratt, with introduction and notes by Dr John Fraser.

PARIS

**Academy of Sciences, January 16**—M de Lacaze Duthiers in the chair.—Swimming movements of the ray fish, by M Maisey. These were investigated by means of chronophotography, ten exposures being made per second. The fish was fixed in position by the head and tail, and the views were taken from the front and the side respectively, the fins being left free.

to move. The photographs show the successive phases of one entire motion of the fins, which consists of a wave like motion beginning in front. Shortly after the anterior portion has been lifted it is depressed, the motion being meanwhile propagated to the lateral portions, and growing in amplitude as the fin grows in breadth. Just before the movement dies out near the tail the process recommences in front. The periodic time was 0.8 seconds. The photographs show a striking likeness to those obtained by chronophotography applied to the flight of birds. M. Marey intends to study the mechanical effect of the action of the fins upon the water, also by the aid of photography. — Microscopic researches on the contractility of the blood-vessels, by M. L. Ranvier. The pericardial membrane of the frog was placed on the disc of the slide cell in one or two drops of peritoneal serum. It was kept extended by a platinum ring, electrodes of tin foil were placed in connection, and a cover glass was fixed over the whole with paraffin. Thus mounted, the smooth muscular fibres and the internal elastic sheath are well seen. On connecting the induction coil with the electrodes, the muscular fibres contract as soon as the current is strong enough. At the same time, the folds of the internal sheath become more pronounced and finally touch, thus effacing the passage through the small artery. On breaking the current, the artery gradually regains its original diameter. If the current is not sufficiently strong for producing a regular contraction, some of the segments contract, while others are at rest. But the zone of contraction is never displaced, and, if interrupted, will reappear at the same place on reestablishing the current. Nothing corresponding to a peristaltic motion can be produced by direct electrical excitement. In none of the experiments, even with the strongest currents, was it possible to detect any signs of contraction in the capillaries. — On the sum of the logarithms of the first numbers not exceeding  $x$ , by M. Cahen. — On differential equations of a higher order, the integral of which only admits of a finite number of determinations, by M. Paul Painlevé. — On linear differential equations with rational coefficients, by M. Helge von Koch. — Electric waves in wires, depression of the wave propagated in conductors, by M. Birkeland (see *Wiedemann's Annalen*, abstract). — On the minimum perceptible amount of light, by M. Charles Henry. This was estimated by Aubert at  $\frac{1}{1000}$  of the light of the full moon. This is about a thousand times too great, as proved by some measurements made with the zinc sulphide (phosphorescence) photometer previously described. The corrected formula for the rate of loss of luminosity of the sulphide is  $10^6(t - 18.5) = 1777.8$ , which agrees even with the longest observations, and is theoretically justified by M. Henri Becquerel. The minimum perceptible amount of light was determined by noticing the time at which the eye, previously kept in the dark for one hour, could only just distinguish the light emitted by the phosphorescent substance, taking care to test for illusions by the successive interposition of ground glass screens. The time thus found was four hours, giving an amount of light of  $29 \times 10^{-9}$  standard candles at 1 m. If the eye is previously kept in the dark during varying periods, the minimum varies inversely as the square of the time during which it is kept dark. — On phosphorescent sulphide of zinc, considered as a photometric standard, by the same. Careful tests showed that the light emitted by zinc sulphide at a given instant is independent of the distance of the illuminating magnesium ribbon, of the time of illumination, and of the thickness of the layer, and is also uniform in samples prepared under different conditions, thus exhibiting all the requisites of a secondary photometric standard. — On an acid platino nitrate of potassium, by M. M. Vèze. — Decomposition of chloroform in presence of iodine, by M. A. Besson. — On some ethers of homopyrocatechine, by M. H. Cousin. — On the determination of phosphorus in iron and steel, by M. Adolphe Carnot. The new method, based like most others on the employment of ammonium molybdate, differs from them in the mode of separation of the silicon, which is effected by sulphuric acid, in the process of destruction of the carbon compounds, brought about by chromic acid, and in the nature of the final compound, which is not magnesium pyrophosphate, but dry phosphomolybdate of ammonia, which only contains 1.628 per cent. of phosphorus, thus ensuring a greater accuracy in the quantitative estimation. — Losses of nitrogen in manure, by MM. A. Muntz and A. Ch. Guard. — Researches on the localisation of the fatty oils in the germination of seeds, by M. Eugène Mesnard. It appears that, except in the grasses, the fatty oil

is not specially localised. It is in all cases independent of the starch and the glucose, but it appears superposed upon the albuminoid materials in the reserves of ripe seeds.

## BERLIN

Physical Society, December 16, 1892. — Prof. Kundt, President, in the chair. — Dr. Lummer spoke on the principles involved in the use of half-shade polarimeters. He showed that the difference in brightness of the two halves of the field of the instrument depends first on the angle between the two polarising prisms, the less this is the greater being the difference produced by a minimal rotation of the analyzer, and secondly on the power of perceiving minute differences of brightness. In connection with the latter he had made some changes in the Lippich instrument which presented some distinct advantages. — Prof. Goldstein gave an account of some experiments made many years ago, but not yet published. He first dealt with the light which appears at the anode, and which, as compared with that of the cathode, has as yet been but little investigated. As is well known, a cathode consisting of two metals emits rays of different brightness from its two parts, thus for instance the aluminium emits brighter rays than does the silver. When this electrode is used as an anode, the reverse holds good, inasmuch as the anodic light of silver is brighter than that of aluminium. The difference is, however, only observed in rarefied oxygen, and does not exist in a hydrogen tube, and is hence due to oxidation of the silver. The second set of experiments dealt with Crookes' supposed reciprocity deflection of cathodic rays of similar direction. The speaker had shown, by shielding one of the electrodes, that the deflection is apparent, not real. The change in the path of the cathodic radiation is due entirely to the effect of the second electrode upon the rays emitted by the first.

## TROPICAL AGRICULTURE

*A Text-book of Tropical Agriculture* By H A Alford Nicholls, M D, F L S, C M Z S, with illustrations, pp 312 (London Macmillan and Co, 1892)

THIS text-book is the English edition of a work that has already received high commendation from the Government of Jamaica. The Government of this now prosperous colony, in pursuance of a policy (which may well be followed by other colonies) offered a premium of one hundred pounds for the best text-book of Tropical Agriculture adapted for the use of colleges and higher schools in the colony. The award was made to Dr Nicholls's manuscript, and after the publication of the work in Jamaica it was adopted also as a text-book by the Government of other colonies, so that its value has been practically estimated beforehand. The author's qualifications for the task he has undertaken may be gathered from the following —

"Twelve years ago, when he had to direct his attention to tropical agriculture, there was no practical book that he could turn to for help in all the difficulties that were constantly cropping up in his path. Knowing, therefore, the obstacles that usually beset the inexperienced planter who is not content to follow the old grooves of unscientific agriculture, the author has so written the second part of this book as to afford the information he needed greatly in his own planting novitiate. This has rendered it necessary to enter into details, which to the experienced agriculturist may appear superfluous, but the book is really intended as a guide to the young and unlearned to whom such details are likely to be of essential service."

As an introduction to tropical agriculture this book supplies a want long felt. There are several works of a technical character treating of old and well-established industries such as sugar, tea, coffee, cacao. None of these, however, could be adopted as text-books in schools. Indeed they all presuppose such a close acquaintance with the principles and terminology of tropical agriculture that they appeal to a very limited class of readers. Hitherto, tropical agriculture, to a large extent, has borrowed most of its methods from the agriculture of temperate climates and adapt them, as well as it could, to the very different circumstances of the torrid zone. The result has been by no means satisfactory. In tropical regions effects follow cause so rapidly that methods admirably adapted to the cold, sluggish climates of northern countries are most injurious when too closely followed in the tropics. As instances we may cite the serious effects on climate following the extensive cutting down of forests, and the wholesale washing away of surface soil from land under permanent cultivation by the destructive influences of tropical rains. The merit of Dr Nicholls's book lies in the fact that its precepts are directly based on his own experience, and he appeals so effectively to the intelligence of his readers that they cannot fail to be instructed. The work is divided into two parts:—Part I. deals with the elementary principles of agricultural science and discusses amongst other subjects the origin and composition of soils, the nature of plant life, the controlling influence

of climate, the action and constituents of manures, the rotation of crops, the drainage of soils, irrigation, tillage operations, pruning, budding, and grafting. In Part II there is treated the application of these principles to some of the chief of the various cultivations undertaken in tropical countries. As examples we may mention that there are detailed accounts given of the methods found most successful in the cultivation of coffee, cacao, tea, sugarcane, fruits, spices, tobacco, drugs, dyes, tropical cereals, and such food plants as cassava, arrowroot, yams, sweet potato, tania (*Colocasia*).

The book is intended also, according to the preface, to be of service to peasant proprietors, owners of small estates, and to those [European] settlers who from time to time may wish to make their homes in the tropics. It is just these people who are now building up the new prosperity of the West Indies by means of what are called "minor industries" or *la petite culture*—which the French have found so remunerative in many of their colonies. To guide and instruct the mass of small cultivators in the West Indies has been the dream of the most enlightened Governors, such as Sir John Peter Grant, Sir Anthony Musgrave, Sir William Robinson, and others that have ruled there for the last thirty years. The intelligent settlers of European origin can very well take care of themselves, but the mass of the small cultivators are black people. They have, it is true, received some education, and they are not wanting in intelligence in regard to what concerns their own interests, but their methods of cultivation have, hitherto, been of the rudest and most destructive description. They crop the land year after year without any manuring, and when it is thoroughly exhausted they move on, when they can, to fresh land, and treat that in exactly the same way. Thus in the black man's system of cultivation the rotation is of land, and not of crops, and the future has to take care of itself. This is a relic of the times of slavery, when the negroes were allowed as much land as they cared for—out of reach of sugar cultivation—to grow provisions for their own subsistence. It is now necessary to change the whole character of the black man's cultural methods, or the rich and fertile lands still left in the West Indies will be absolutely ruined. Generally only the lowest class of negroes have hitherto been attracted to field work. The education given to these people is responsible for something of this result, for it leads them, in too many cases, to regard labour in the field as degrading, and almost a return to a state of slavery. The sharper and more intelligent boys, when they leave school, are drawn away to seek a precarious existence as clerks in stores or as small shopkeepers, where they seldom do more than copy the weaknesses and vices of the whites, while, according to our author, if they took to the land, and had a right understanding of agricultural methods, they "need never despair of becoming prosperous." In the more advanced colonies, such as Jamaica, there is a disposition to establish industrial schools and train the younger generation in approved methods of cultivation, and lead them to regard the tillage of the soil as a more honourable and remunerative occupation than petty trading. We may hope that the claims of industrial education will become more widely recognized, not only in the West Indies but in all our tropical colonies where native races have to be dealt

with In the meantime colleges and schools must prepare competent instructors for the work, and for both teacher and taught this book is an admirable starting-point. In it the whole field of small industries is well covered, and the language is clearly expressed and well chosen. As an example of the author's treatment we find under manures (p. 49) —

"The land must be regarded by the planter as a bank in which he has opened an account. If he continually draw cheques on the bank, and make no fresh deposit to meet the drain, he will sooner or later come to the end of his capital, and the same argument applies to the soil. In cacao and coffee cultivation in the West Indies, particularly on lands of peasant proprietors, one often sees the planter take away crops year after year, whilst he does next to nothing to make up for the heavy drain on the land, and then, after a time he finds he gets very small crops, and he thinks the fault lies with the trees, or that the soil is not adapted to the cultivation, whereas the fault is entirely his own, as he has gone on taking away from the soil without putting anything back." Again, "the great fault hitherto committed by tropical planters has been the confining of their attention to one kind of cultivation on their land. If several different crops were taken off alternately, as in a system of rotation, or grown in different parts of the land, where the soil and climate prove suitable, the planter would be in a much better position than he is now, for he would not 'have all his eggs in one basket'."

It is noticed that the valuable services rendered to colonial industries by Kew and by the various botanical institutions in correspondence with Kew are fully recognised. Further, the dedication of this first Text-book of Tropical Agriculture to Sir Joseph Hooker is a compliment not only to his own distinguished services, but also to those of his father, for both in their day took the deepest interest in the West Indies. It must be gratifying to the late Director of Kew to learn "in the quiet of his retirement that the influence of his work lives on and bears fruit even in the far-away field" of the West Indies.

D M

### CELLS THEIR STRUCTURE AND FUNCTIONS

*Die Zelle und Das Gewebe, Grundsätze der allgemeinen Anatomie und Physiologie* Von Prof. Dr. Oscar Hertwig (Jena: Gustav Fischer, 1892)

TEXT-BOOKS on Histology introduce the structure of the tissues to their readers by a chapter on cells, and the best treatises on Anatomy, either human or comparative, usually devote some pages to the consideration of these, the most elementary of all the tissues. As so many important advances have been made of late years in our knowledge of the structure of cells and their contained nuclei, of the properties of protoplasm, of the division of nuclei and the part played by the nucleus in cell multiplication, and of the influence exercised by cells in the problems of hereditary transmission, the time has obviously arrived for the production of a treatise devoted to the description of the cell in its various aspects, observational as well as speculative. No better expositor of the subject in all its bearings could be found than Prof. Oscar Hertwig, who has himself conducted important investigations on this branch of anatomy. The book now

before us treats of the general anatomy and physiology of cells, and is to be followed by a second volume, in which the origin and physiological properties of the tissues are to be expounded, as well as their structure.

After a sketch of the history of the cell theory and of the theory of protoplasm, in which, as is so often the case in German text-books, the names of British observers and authors are conspicuous by their absence, he defines a cell to be a little clump of protoplasm which incloses a specially-formed constituent, the nucleus; a definition which accords with those previously made by Leydig and Max Schultze. He then describes at considerable length the characters of protoplasm, both anatomical and physiological, and the chemico-physical and morphological properties of the nucleus. In a short section he discusses the question, Do elementary organisms exist without nuclei? i.e. Can you have little clumps of non-nucleated protoplasm pursuing an independent life? As is well known, Haeckel described organisms of this simple character, as cytodes, and gave Monera as an example, but Hertwig is disposed to think that such non-nucleated organisms have not been definitely demonstrated in the animal kingdom, and he quotes Butschli's observations, which seem to show that even in such micro-organisms as Bacteria a differentiation of a nucleus from surrounding protoplasm can be distinguished.

Two important chapters are written on the movements of protoplasm, of cilia, of flagella, of spermatozoa, on contractile vesicles, and on the irritability of protoplasm under the stimulus of heat, light, electricity and several kinds of mechanical and chemical irritants. The fifth chapter is devoted to the consideration of the nutritive changes and formative activity in cells. Illustrations are given of the power possessed by certain unicellular organisms of taking into their substance and digesting solid bodies of various kinds, and an account is appended of the important observations of Metchnikoff on phagocytosis.

Chapters six and seven are occupied with a description of the multiplication of cells, their mode of division, and the method of fertilization. The process of karyokinesis is described at some length and in its various phases, in clear and precise language, and with an amount of illustration which enables the reader to follow without difficulty this complicated process. The influence exercised by the nucleus, and the part which it plays in the process of cell multiplication, has now been put by the labours of many investigators on a basis of observation, both as regards plants and animals, such as cannot be controverted, and the accuracy of the generalization made half a century ago, both by Martin Barry and John Goodsir, that young cells originate through division of the nucleus of a parent cell, has been amply established.

Dr Hertwig also recites observations which seem to show that the nucleus does more than act as a reproductive centre within the cell, but also takes a part in cell nutrition. This function of the nucleus was also contended for by Goodsir, but during the period when protoplasm was regarded as the essential element in nutrition or secretion, the claim of the nucleus to take any share in this phase of cell activity was summarily put aside. Recent observations have, however, shown that

"clumps of protoplasm, removed from either a unicellular plant or animal, in which no nucleus is present, although capable of living, and retaining their irritability and power of movement for some time, yet neither grow, nor form a cell membrane, nor have the same power of digesting bodies introduced into their substance, as is possessed by a clump of protoplasm which has retained the nucleus. The nutritive activity of the protoplasm would appear, therefore, to be under the influence of the nucleus.

The volume concludes with a chapter on the cell in its relation to theories of heredity. The author, as is now the prevailing opinion amongst biologists, contends that the nucleus is the conveyer of hereditary properties, and that the offspring is a mixed product of both its parents, derived from the ovum and the sperm cell. In the course of this chapter he discusses the views of Darwin, Spencer, Nageli, Weismann, and De Vries, and suggests the employment of the term "Idioblasts" for the minute elementary particles, which Darwin called "gemmules" in his hypothesis of pangenesis, and which he conceived to be capable of transmitting hereditary characters to succeeding generations.

### THEORETICAL MECHANICS

*Elementary Mechanics of Solids and Fluids* By A. L. Selby, M.A. (Oxford: Clarendon Press, 1893.)

AT a period when we are bound to recognize the influence exerted by the examinations of the various educational institutions and of those controlled by other more or less influential examining bodies, we may be excused, on the arrival of a new work, for stating whether or not, and to what extent, it is adapted to their requirements. The book before us does not appear to have been intentionally written for examination purposes, and perhaps on this account it will be all the more welcome. Its purpose, however, is very distinct. It is intended for those students who are desirous of reading mechanics as an introduction to a study of physics. So far, therefore, as its suitability for examinations is concerned, we can heartily recommend it to those who wish to qualify in this particular branch of science, while at the same time it will be read with great benefit by that class of students who desire a thorough knowledge of the portions generally included under the head of Theoretical Mechanics.

In the study of such subjects as the book treats of, the amount of knowledge which the reader may have of mathematics will, to a considerable extent, be a measure of his success. The author expresses a hope that an acquaintance with the elements of algebra and geometry will suffice; but, while not wishing to reduce the usefulness of the book, but rather to direct it into proper hands in which it will be read with greater advantage, we think it would be nearer the mark to say that a thorough knowledge of elementary algebra and a considerable acquaintance with elementary trigonometry are necessary. Certainly the definitions of the trigonometrical ratios will be found in an appendix, but it will be far better if the student has lived with and used these for some time.

Possessing these requirements, he will appreciate and even admire the broad, yet concise nature

of the treatment generally, and with regard to this matter we may say that we are unacquainted with any elementary text-book better calculated to create a desire for precise and full ideas. That this is requisite for a study of physics perhaps more than any other subject, no one will deny.

The first chapter of the book is occupied with a consideration of Kinematics, and in it will be found a careful exposition of the displacement, velocity, and acceleration to which a body may be subjected, due attention being drawn to what is necessary for a full representation of them. The appendix following this contains some geometrical theorems and definitions for subsequent use. Then follow the usual chapters on the laws of motion, work, and energy, centre of gravity, moments of inertia, and simple machines. A chapter on gravitation will be read with interest, preceded as it is by an explanation of some of the geometrical properties of the ellipse. Kepler's laws of planetary motion are dealt with; in addition to other relevant matters which do not usually find their way into elementary text-books.

The subject of elasticity also receives a somewhat more extensive treatment than is usually given to it. The various kinds of stress and strain which a body may undergo are explained, together with the relation between stress and strain. At the end of the book we find what is included under the second head of the title. The various principles and laws which refer to fluids, and some of the machines and instruments which depend on them for their action, are enumerated and explained, while the interesting subject of capillarity has a separate chapter devoted to it.

To an appreciative reader it is a source of satisfaction to observe the care the author has exercised when dealing with the important matter of definitions and units—fundamental and derived. A chapter on units and their dimensions is furnished at the end.

A good selection of examples, bearing on the matter treated therein, will be found at the close of the chapters.

Many portions of the book are characterized by a decided freshness of treatment, and we have little doubt that the careful reader will find many little points which are satisfying, in that they tend to widen the somewhat restricted views he may have previously held, and these will be all the more apparent should his mind be of a mathematical turn.

G. A. B.

### OUR BOOK SHELF

*Magnetism and Electricity* By R. W. Stewart. (London: W. B. Clive and Co.)

THE book forms one of the University Correspondence College Tutorial Series, and is "primarily written for the use of candidates for the Matriculation, Intermediate Science, and Preliminary Scientific Examinations of the University of London." The author is evidently familiar with the difficulties which usually occur to students, and the best portions of the book are those in which efforts are made to elucidate some of the more general errors. The descriptions of apparatus and phenomena are, however, generally rather short and meagre, while the diagrams are frequently inadequate for a work of this sort. Little is written to help the beginner to perform experiments for himself; in fact, descriptions of many important instruments are omitted—for example, the Wheatstone

Bridge—and to students having no access to a laboratory little satisfaction will be given when told "The details of the construction and practical use of the different forms of Wheatstone's Bridge used in the measurement of resistance are best learnt in the laboratory, and for this reason we shall not give any further description of the arrangement."

In many instances the student is driven through a mass of theory before he has a fair idea of the general phenomena, thus in the introductory chapter on "Current Electricity," after a six-line description of a simple cell and current, over two pages are occupied in proving that the effects produced could be explained by the dissociation and procession of the hydrogen and oxygen atoms. The work is generally remarkably free from errors and misprints, but one occurs in the explanation just mentioned. The attraction of zinc for oxygen is said to be much greater than that of the copper, while later the zinc is also considered "to *repel* hydrogen less." Here, and in many other instances, the words to be emphasised are printed in italics. Another mistake will be found on pp 168 and 169, where in comparing, by the method of oscillations, the field due to a magnet with that of the earth, the author starts with the equation  $\frac{I+H}{I} = \frac{n_1^2}{n^2}$

instead of  $\frac{I+H}{H} = \frac{n_1^2}{n^2}$ , and reasoning correctly from this false hypothesis, he deduces false results, while the answer to Ex 8 on this part of the subject appears incorrect. Fig 13, p 201, in illustration of Oerstedt's experiment, is not correctly drawn.

The arrangement of "calculations" and examples at the end of each chapter must prove extremely useful to students possessing beforehand an elementary knowledge of the general phenomena, and to such, rather than to the very beginner, the book may be commended. H S J

*Manners and Monuments of Prehistoric Peoples* By the Marquis de Nadaillac. Translated by Nancy Bell (N D'Anvers) (New York and London G P. Putnam's Sons, 1892)

A BOOK summing up in a popular style all that is now known with regard to prehistoric man would probably be welcomed by a tolerably large class of readers. The present work does not quite supply the kind of summary that is wanted. The author does not distinguish with sufficient clearness between the various periods with which he deals, he indulges too freely in talk of a vaguely moralising tendency, and some of his statements do not accord with the conclusions of the best authorities. Speaking of the Round Towers of Ireland, for instance, he says, "According to the point of view of different archæologists, they have been called temples of the sun, hermitages, phallic monuments, or signal towers." The reader is thus left to suppose that the question is still open, whereas all competent students of the subject accept the theory of the late Mr. Petrie, a theory which the Marquis de Nadaillac does not even mention. However, the author has presented a large number of interesting facts in the course of his exposition, and there are occasional passages in which he brings out very well the attractive elements of some of the more fascinating departments of archæology.

### LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. No notice is taken of anonymous communications.]

#### Two Statements.

In a letter addressed to the *Daily Chronicle*, dated January 15, 1893, Prof. Karl Pearson makes two statements respecting my opinions and grounds of action:

NO. 1214, VOL. 47]

"As in society at large, so in academic matters, his mode of insuring progress is unlimited individual competition," and again

"he is an individualist in all matters."

Seeing that in an essay "On Administrative Nihilism," published twenty-two years ago, and in another on "Government Anarchy or Regimentation," published in 1890, I have done my best to combat the doctrine Prof. Pearson attributes to me, I shall be glad to know what justification he has to offer for so grave a misrepresentation. The purpose of it is obvious.

T H HUXLEY

Hoddeslea, Eastbourne, January 29

#### A Meteor

THE following is taken from the *Pretoria Weekly Press* for January 7: "A few evenings ago a meteor of unusual size and brilliancy was observed at Bloemfontein shooting right across the eastern sky. It looked like a rocket of a greenish colour, and burst in a shower of sparks in the south-east. The spectacle was much admired by those who were fortunate enough to witness it."

This meteor, as seen in South Africa, appears to have had many points in common with a similar one seen in England about the same time, and reported by several observers in the *Daily Press*.

W L. DISTANT

Purley, Surrey, January 31

#### "Hare-lip" in Earthworms

ATTENTION has recently been drawn by Prof. Andrews (*American Naturalist*, September, 1892) and myself (*Science Gossip*, 1892) to some abnormal conditions of life among the terrestrial annelids. I have now to place on record a totally new appearance, which is, I think, very aptly expressed by the term "hare-lip." The worm which I have had under examination presented the peculiarity figured below, and when alive and in motion suggested to my mind most forcibly the appearance which we associate with the name I have adopted.

The specimen in question belongs to the genus *Allolobophora*, in which genus, so far as my experience goes, almost all the abnormalities are found. The genus *Lumbricus*, it should be observed, is very seldom, if ever, known to present any of these peculiarities. Hitherto the Long worm (*A. longa*, Ude)

Diagram of the anterior portion of green worm (*Allolobophora chlorotica* Savigny), showing abnormal appearance of lip (*pr*), peristomium (*per*), and three succeeding segments, seen from above, and enlarged.

has been most prolific of bifurcated heads and tails. Now we find the Green worm (*A. chlorotica*, Savigny) yielding new features for study. The peculiarities which have presented themselves in former times have usually taken the form of a second head or a supernumerary tail. In this instance there is no off-growth, however, but merely a malformation of the anterior segments. One might have supposed that the peculiarity was due to accidental causes. It would have been easy to suppose that the head had been split, and then the wound had healed, leaving a seam down the middle. I observed, however, that each of the three specimens of the Green worm which I received from Cork (Ireland) showed some abnormal feature, and there were other peculiarities in this particular specimen which indicated that we had to deal with a congenital rather than an accidental condition of things.

As this is the first occasion on which such a peculiarity has been recorded or figured, I prefer to leave all speculation as to the cause out of the question. We need a good deal more research before we can deal satisfactorily with the biological problems involved in such appearances. As a help towards this, I bring together here a list of all those works which have come under my own and Prof. Andrews's notice, in which abnormalities in annelids are recorded—

HILDERIC FRIEND

### The Zero Point of Dr. Joule's Thermometer

IN the course of a discussion on "Exact Thermometry" I described (*NATURE*, vol xli p 488) the results obtained by heating thermometers for a considerable time to 280° and 356°, and pointed out by means of a diagram that at 356°, after about ten hours, the rise of the zero point became—at any rate approximately—a rectilinear function of the logarithm of the time, though at 280°, even after more than 300 hours' heating, the rise appeared to be rather more rapid than would correspond to such a simple relation.

Dr. Joule observed the rise of the zero point of a thermometer at the ordinary temperature during a course of no less than thirty-eight years ("Scientific Papers," vol I, p 558), and it occurred to me that it would be of interest to ascertain the relation to the logarithm of the time in this case also.

The following table contains the dates of Dr. Joule's observations, the total number of months from the date when the first reading was taken; the corresponding logarithms, the total rise of the zero point in scale divisions (13 divisions to 1° F), the total rise calculated from the formula  $R = 6.5 \log t - 4.12$ , where  $t$  is the time in months; and lastly the differences between the observed and calculated zero points.

Date.	Time in Months.	Log $t$	Total rise of zero point in scale divisions.

NO. 1214, VOL. 47]

The agreement between the observed and calculated values is certainly remarkable, and the + and - differences are evenly distributed.

Ten years have now elapsed since the last reading was taken, and if the thermometer is still in existence it would be of great interest to know what further rise has taken place in its zero point. According to the equation the reading should now be 13.86.

University College, Bristol, January 20

### THE APPROACHING SOLAR ECLIPSE, APRIL 15-16, 1893

THE total solar eclipse of April 15-16, 1893, is not only one of the longest of the century, but is the last of the century from which we are likely to get any addition to our knowledge of Solar Physics. The longest duration of totality of this eclipse is 4 minutes 46 seconds, and as the path of the moon's shadow lies to a great extent on land, there is a considerable choice of possible stations with long durations of totality. Commencing in the Southern Pacific the line of totality passes in a north-easterly direction and enters Chili at Charañah in 29° southern latitude, crosses the South American continent, and issues at Para Cura, a village near Ceara, at the north-east corner of Brazil, in latitude 3° 40' south. It crosses the Atlantic at its narrowest part and enters Africa at Point Palmerin, near Joal, almost midway between Bathurst and Dakar, and in latitude 14° north, the shadow finally leaving the earth in the interior of Northern Africa. The eclipse will be observed by several parties of astronomers in Chili, Brazil, and Africa, there being almost absolute certainty of fine weather in Chili and Africa, and a reasonable probability in Brazil.

The English arrangements to observe the eclipse have been made by a joint committee of the Royal Society, the Royal Astronomical Society, and the Solar Physics Committee of the Science and Art Department, South Kensington. Dr A. A. Common, LL.D., F.R.S., undertaking the duties of Secretary. Two expeditions will be sent from England, one to Africa and the other to Brazil, the expenses being defrayed by a grant of £600 from the Royal Society.

The African expedition will be in charge of Prof. T. E. Thorpe, and will consist of Prof. Thorpe, Mr. A. Fowler, Mr. Gray, and Sergeant J. Kearney, R.E. The Brazilian expedition will be in charge of Mr. A. Taylor, who will have with him Mr. W. Shackleton.

Prof. Thorpe and his party will leave Liverpool by the British and African mail steamer on March 18th, arriving at Bathurst on April 2nd. They will be met at Bathurst by a gunboat kindly placed at the disposal of the expedition by the Admiralty, and will be conveyed at once to Fundium, a station on the Salum River, about sixty miles from Bathurst; this being the station selected by the Committee from the three which were offered by the French Government. The gunboat will remain with the expedition, and the officers and crew will assist in the preparations for and in the actual observations of the eclipse. After the eclipse the party will be taken to Bathurst on the gunboat, and will return to England by a British and African mail steamer, if one is available. From the time-tables of the steamers now published it appears, however, that there will not be any mail steamer available until the end of April, and in this case a cruiser will meet the party at Bathurst and bring them to the Canary Islands or to Gibraltar, from either of which places they will be able to return by mail steamer, arriving in England early in May.

The members of the expedition to Brazil will leave Southampton by the Royal Mail steamer on February 23 for Pernambuco, arriving at the latter place on March 12. They will take passage by the local mail steamers to Ceara, at which place they will arrive about March 20.

The Brazilian Government are willing to place a war vessel at the disposal of the foreign expeditions to observe the eclipse, and it is hoped the English observers will be able to avail themselves of the privilege thus gracefully offered. The station selected is at Para Cura, on the coast about forty miles west of Ceara, and the party will rely upon obtaining any necessary help from the Brazilian authorities and from local assistants. The observers will return from Pernambuco by the Royal Mail steamer due to leave there on April 22, and expect to be in England on May 5.

The objects of the expeditions are—

(1) To obtain visual photometric measures of the light of the corona

(2) To obtain photographs of the corona with the four-inch lenses of a little over sixty inches focus belonging to Captain Abney, which were successfully used in Egypt (1882), Caroline Island (1883), Granada (1886), and Salut Isles (1889), in order to continue the series

(3) To obtain enlarged photographs of the corona with small photographic action, so as to show details of the structure of the brightest parts, *æ* those nearest the sun

(4) To measure the photographic intensity of the light of the corona, by direct comparison with standard intensity scales placed on the margins of the plates used for the negatives to be obtained under sections 2 and 3

(5) To obtain photographs of the spectrum of the corona. These spectra will be obtained on three different plans—

(a) With integrating spectroscopes, where no collimator is used and the prism or prisms are placed directly in front of the object glass of the photographic camera

(b) With ordinary slit spectroscopes, the slit being arranged as a radius of the sun

(c) With ordinary slit spectroscopes, the slit being arranged as a tangent to the sun's limb

The first of these objects will be attempted only at the African station; Prof. Thorpe and his assistant, Mr Gray, making the observations. Their equipment will consist of a six-inch Simms equatorial of seventy-eight inches focus (lent from Greenwich) fitted with special photometric apparatus lent by Captain Abney. The observations will be made on essentially the same plan as that pursued by Prof. Thorpe at Hog Island, near Granada, in 1886, separate portions of the corona being compared with a standard glow lamp by means of a Bunsen photometer. An integrating box for measuring the total coronal light with as little light from the sky as possible, and an ordinary Bunsen's bar photometer will also be used, these being entrusted to officers of the gunboat.

As regards objects 2, 3, and 4, duplicate apparatus has been arranged for use at the two stations

A photoheliograph mounting from Greenwich has been lent for Brazil, and an exactly similar instrument from South Kensington for Africa. On each of these mountings a specially designed new double tube will be fixed. An Abney lens will be mounted in one compartment of each of these tubes, and this, with a focal length of sixty inches, will give pictures on the scale of rather more than half an inch to the moon's diameter. In the other compartment a four-inch Dallmeyer photoheliograph lens will be mounted in combination with a specially-constructed two-and-a-half-inch Dallmeyer negative lens of eight inches negative focus; this arrangement giving, with a total length of sixty-eight inches, pictures on the scale of over one-and-a-half inches to the moon's diameter. This latter arrangement is essentially the same as that of Dallmeyer's new telephotographic lens. It will be so arranged that the ratio between the photographic effect of the Abney lens and the new combination will be as 10 : 1

Special plate holders have been made to fit the double tubes, each of these plate holders carrying two plates,

which will be exposed simultaneously to the images formed by the Abney lens and the enlarging combination. The six separate exposures, giving twelve photographs, will be so arranged that the longest exposed pictures with the enlarging combination will have received the same photographic action as the shortest exposed pictures with the Abney lens. The whole of the pictures will thus form a continuous series, all the short exposures in the series having a direct enlargement of three diameters

In Brazil Mr Taylor will take charge of this double instrument, and in Africa the similar instrument will be entrusted to Sergeant Kearney. On the night before the eclipse intensity scales for object 4 will be impressed by the use of standard lights and specially-constructed scales kindly supplied by Captain Abney on all the plates to be exposed to the corona. The plates will be developed at the stations as soon as convenient after the eclipse, experience on previous occasions, both by English and American observers, having shown that it is impossible to repack undeveloped plates after exposure in the tropics, and bring them home without serious deterioration

Similar spectroscopic work is to be carried out at the two stations. For the integrating spectroscope in Africa Mr. Fowler will use a six-inch objective prism with a six-inch photographic lens of about nine-feet focus, mounted on an equatorial stand, belonging to Prof J. Norman Lockyer, and kindly lent for the expedition. At the Brazilian station Mr Shackleton will use two three-inch prisms in front of a three-inch photographic lens of about two-feet focus; the spectroscope, which belongs to South Kensington, being arranged horizontally and used with a ten-inch heliostat, also lent by the Science and Art Department. Very short exposures will be given at each station at the commencement and end of totality, so as to obtain, if possible, the very numerous bright lines which have been observed in the chromosphere, and exposures of from 5 to 45 seconds will be given during totality

In Africa the radial and tangential slit spectroscopes will be mounted together on the Corbett equatorial stand lent from Greenwich, the spectroscopes used belonging to the Royal Society. Mr Fowler and Sergeant Kearney will erect and adjust these instruments, but the actual exposure, which will extend through the whole of totality, will be made by an officer of the gunboat who will be placed in charge of the instrument. In Brazil the radial and tangential slit spectroscopes will be mounted horizontally and used with a second ten-inch heliostat lent by the Science and Art Department. The erection and adjustment will be made by the observers, but the actual exposure during totality will be entrusted to a local assistant. Orthochromatic plates will be used for all the spectroscopic work, the spectra obtained extending from above D into the ultra-violet

Briefly summarised, the English programme is as follows—

In Africa—Prof T. E. Thorpe, assisted by Mr Gray and local assistance—Photometric measures of the visual intensity of the corona with the equatorial photometer, the integrating photometer, and the bar photometer; Mr Fowler—The six-inch integrating spectroscope; Sergeant Kearney—the Abney and Dallmeyer coronagraphs, local assistance—the radial and tangential slit spectroscopes.

In Brazil:—Mr Taylor, the Abney and Dallmeyer coronagraphs, Mr Shackleton, the three-inch two-prism integrating spectroscope, local assistance, the radial and tangential slit spectroscopes

It is not yet decided whether one of the 20-inch mirrors of 45-inches focus specially constructed to photograph the faint extensions of the corona during the eclipse of 1889 (December 21–22) will be taken to Africa. If so it will be entrusted to a local assistant. It was originally intended to use one of these in Africa, and it was hoped that one would be used by the Harvard College

Observatory party, which is to occupy a station in Chili, but Prof W. H. Pickering writes that difficulties of transport will prevent him from taking the 20-inch mirror he has at Arequipa to the Harvard station, and owing to this and to the already large programme of the English party in Africa there is some doubt whether they will take one of the mirrors. April being the middle of the rainy season in Brazil, it is not deemed advisable to send one of the mirrors to that station.

The duration of totality at Para Cura is four minutes forty-four seconds, the altitude of the sun being between 70° and 80°. At Fundium the totality lasts four minutes eight seconds, the altitude of the sun being about 54°.

The Joint Eclipse Committee having arranged the expeditions and the general scheme of work, final details as to the actual operations have been left to a sub-committee consisting of the Astronomer Royal, Captain Abney, Mr H. H. Turner, Prof Thorpe, Mr A. Taylor, and the secretary, Dr Common. Prof Lockyer, previous to leaving England for Egypt, determined the exposures to be given by Messrs Fowler and Shackleton with the integrating spectroscopes. These, with the final instructions to observers drafted by the sub-committee, will be published in due course.

At present very few details are available as to the actual work to be undertaken by foreign observers. The Harvard College Observatory expedition to Chili has already been mentioned. Prof Schaeberle, of the Lick Observatory, has already started for Chili, and will use a six-and-a-half-inch equatorial, a five-inch horizontal photoheliograph of forty-feet focus, and a Dallmeyer portrait lens. He will be assisted by Mr Gale, an amateur, from Paddington, N. S. W. A Chilean party will also observe the eclipse in Chili.

At Para Cura there will probably be two or three American parties, one being announced as probably under Prof H. S. Pritchett, from Washington University, St. Louis, and another will probably be brought to that station by Prof David P. Todd. A Brazilian party will also observe. The Bureau des Longitudes, Paris, are sending a complete expedition to Joal, in Africa, under MM. Deslandres and Bigourdan, the latter observer having already started for his station. The work undertaken will be to obtain photographs of the corona and of its spectrum. M. de la Baume Pluvinel will also go to Joal to photograph the corona. At present we have not heard of any Italian expedition, but it is hoped that Prof Tacchini will be able to arrange to observe the eclipse.

A. TAYLOR

### MEASURE OF THE IMAGINATION<sup>1</sup>

THE first perceptible sensation is seldom due to a solitary stimulus. Internal causes of stimulation are in continual activity, whose effects are usually too faint to be perceived by themselves, but they may combine with minute external stimuli, and so produce a sensation which neither of them could have done singly. I desire now to draw attention to another concurring cause which has hitherto been unduly overlooked, or only partially allowed for under the titles of expectation and attention. I mean the Imagination, believing that it should be frankly recognised as a frequent factor in the production of a just perceptible sensation. Let us reflect for a moment on the frequency with which the imagination produces effects that actually overpass the threshold of consciousness, and give rise to what is indistinguishable from, and mistaken for a real sensation. Every one has observed instances of it in his own person

<sup>1</sup> Extract from a lecture on "The Just-Perceptible Difference," delivered before the Royal Institution, on Friday, January 27, by Francis Galton, F.R.S. We hope to give next week an extract on "Optical Continuity."

and in those of others. Illustrations are almost needless, I may, however, mention one as a reminder; it was current in my boyhood, and the incident probably took place not many yards from where I now stand. Sir Humphrey Davy had recently discovered the metal potassium, and showed specimens of it to the greedy gaze of a philosophical friend as it lay immersed in a dish of alcohol to shield it from the air, explaining its chemical claim to be considered a metal. All the known metals at that time were of such high specific gravity that weight was commonly considered to be a peculiar characteristic of metals, potassium, however, is lighter than water. The philosopher not being aware of this, but convinced as to its metallic nature by the reasoning of Sir Humphrey, fished a piece out of the alcohol, and, weighing it a while between his finger and thumb, said seriously, as in further confirmation, "How heavy it is!"

In childhood the imagination is peculiarly vivid and notoriously leads to mistakes, but the discipline of after life is steadily directed to checking its vagaries and to establishing a clear distinction between fancy and fact. Nevertheless, the force of the imagination may endure with extraordinary power and be cherished by persons of poetic temperament, on which point the experiences of our two latest Poet-Laureats, Wordsworth and Tennyson, is extremely instructive. Wordsworth's famous "Ode to Immortality" contains three lines which long puzzled his readers. They occur after his grand description of the glorious imagery of childhood, and the "perpetual benediction" of its memories, when he suddenly breaks off into—

"Not for these I raise  
The song of thanks and praise,  
But for those obstinate questionings  
Of sense and outward things,  
Fallings, from us, vanishings," &c.

Why, it was asked, should any sane person be "obstinately" disposed to question the testimony of his senses, and be peculiarly thankful that he had the power to do so? What was meant by the "fallings off and vanishings," for which he raises his "song of thanks and praise"? The explanation is now to be found in a note by Wordsworth himself, prefixed to the ode in Knight's edition. Wordsworth there writes—"I was often unable to think of external things as having external existence, and I communed with all I saw as something not apart from, but inherent in, my own immaterial nature. Many times while going to school have I grasped at a wall or tree to recal myself from this abyss of idealism to the reality. At that time I was afraid of such processes. In later times I have deplored, as we all have reason to do, a subjugation of an opposite character, and have rejoiced over the remembrances, as is expressed in the lines 'Obstinate questionings,' &c." He then gives those I have just quoted.

It is a remarkable coincidence that a closely similar idea is found in the verses of the successor of Wordsworth, namely, the great poet whose recent loss is mourned by all English-speaking nations, and that a closely similar explanation exists with respect to them. For in Lord Tennyson's "Holy Grail" the aged Sir Percivale, then a monk, recounts to a brother monk the following words of King Arthur—

"Let visions of the night or of the day  
Come, as they will, and many a time they come  
Until this earth he walks on seems not earth,  
This light that strikes his eyeball is not light,  
The air that smites his forehead is not air,  
But vision," &c.

Sir Percivale concludes just as Wordsworth's admirers formerly had done: "I knew not all he meant."

Now, in the *Nineteenth Century* of the present month

\* Knight's edition of Wordsworth, vol. iv. p. 47

Mr Knowles, in his article entitled "Aspects of Tennyson," mentions a conversational incident curiously parallel to Wordsworth's own remarks about himself — "He [Tennyson] said to me one day, 'Sometimes as I sit alone in this great room I get carried away, out of sense and body, and rapt into mere existence, till the accidental touch or movement of one of my own fingers is like a great shock and blow, and brings the body back with a terrible start'."

Considering how often the imagination is sufficiently intense to stimulate a real sensation, a vastly greater number of cases must exist in which it excites the physiological centres in too feeble a degree for their response to reach to the level of consciousness. So that if the imagination has been anyhow set into motion, it shall as a rule originate what may be termed *incomplete* sensations, and whenever one of these concurs with a real sensation of the same kind, it would swell its volume.

This supposition admits of being submitted to experiment by comparing the amount of stimulus required to produce a just perceptible sensation, under the two conditions of the imagination being either excited or passive.

Several conditions have to be observed in designing suitable experiments. The imagined sensation and the real sensation must be of the same quality, an expected scream and an actual groan could not reinforce one another. Again, the place where the image is localised in the theatre of the imagination must be the same as it is in the real sensation. This condition requires to be more carefully attended to in respect to the visual imagination than to that of the other senses, because the theatre of the visual imagination is described by most persons, though not by all, as internal, whereas the theatre of actual vision is external. The important part played by points of reference in visual illusions is to be explained by the aid they afford in compelling the imaginary figures to externalise themselves, superimposing them on fragments of a reality. The visualisation and the actual vision fuse together in some parts, and supplement each other elsewhere.

The theatre of audition is by no means so purely external as that of sight. Certain persuasive tones of voice sink deeply, as it were, into the mind, and even simulate our own original sentiments. The power of localising external sounds, which is almost absent in those who are deaf with one ear, is very imperfect generally, otherwise the illusions of the ventriloquist would be impossible. There was an account in the newspapers a few weeks ago of an Austrian lady of rank who purchased a parrot at a high price, as being able to repeat the Paternoster in seven different languages. She took the bird home, but it was mute. At last it was discovered that the apparent performances of the parrot had been due to the ventriloquism of the dealer. An analogous trick upon the sight could not be performed by a conjuror. Thus he could never make his audience believe that the floor of the room was the ceiling.

As regards the other senses the theatre of the imagination coincides fairly well with that of the sensations. It is so with taste and smell, also with touch, in so far that an imagined impression or pain is always located in some particular part of the body, then if it be localised in the same place as a real pain, it must coalesce with it.

Finally, it is of high importance to success in experiments on Imagination that the object and its associated imagery should be so habitually connected that a critical attitude of the mind shall not easily separate them. Suppose an apparatus arranged to associate the waxing and waning of a light with the rising and falling of a sound, holding means in reserve for privately modifying the illumination at the will of the experimenter, in order that the waxing and waning may be lessened, abolished, or even reversed. It is quite possible that a person who had no idea of the purport of the experiment might be deceived, and be led

by his imagination to declare that the light still waxed and waned in unison with the sound after its ups and downs had been reduced to zero. But if the subject of the experiment suspected its object he would be thrown into a critical mood, his mind would stiffen itself, as it were, and he will be difficult to deceive.

Having made these preliminary remarks, I will mention one only of some experiments I have made and am making from time to time, to measure the force of my own imagination. It happens that although most persons train themselves from childhood upwards to distinguish imagination from fact, there is at least one instance in which we do the exact reverse, namely, in respect to the auditory presentation of the words that are perused by the eye. It would be otherwise impossible to realise the sonorous flow of the passages, whether in prose or poetry, that are read only with the eyes. We all of us value and cultivate this form of auditory imagination, and it commonly grows into a well developed faculty. I infer that when we are listening to the words of a reader while our eyes are simultaneously perusing a copy of the book from which he is reading, that the effects of the auditory imagination concur with the actual sound, and produce a stronger impression than the latter alone would be able to make.

I have very frequently experimented on myself with success, with the view of analysing this concurrent impression into its constituents, being aided thereto by two helpful conditions, the one is a degree of deafness which prevents me when sitting on a seat in the middle rows from following memoirs that are read in tones suitable to the audience at large, and the other is the accident of belonging to societies in which unrevised copies of the memoirs, that are about to be read, and usually in monotonous, are obtainable, in order to be perused simultaneously by the eye. Now it sometimes happens that portions of these papers, however valuable they may be in themselves, do not interest me, in which case it has been a never-flagging source of diversion to compare my capabilities of following the reader when I am using my eyes, and when I am not. The result depends somewhat on the quality of the voice, if it is a familiar tone I can imagine what is coming much more accurately than otherwise. It depends much on the phraseology, familiar words being vividly represented. Something also depends on the mood at the time, for imagination is powerfully affected by all forms of emotion. The result is that I frequently find myself in a position in which I hear every word distinctly so long as they accord with those I am perusing, but whenever a word is changed, although the change is perceived, the new word is not recognised. Then, should I raise my eyes from the copy, nothing whatever of the reading can be understood, the overtones by which words are distinguished being too faint to be heard. As a rule, I estimate that I have to approach the reader by about a quarter of the previous distance, before I can distinguish his words by the ear alone. Accepting this rough estimate for the purposes of present calculation, it follows that the potency of my hearing alone is to that of my hearing *plus* imagination, as the loudness of the same overtones heard at 3 and at 4 units of distance respectively, that is as about  $3^2$  to  $4^2$ , or as 9 to 16. Consequently the potency of my auditory imagination is to that of a just perceptible sound as 16-9, or as 7 units, to 16. So the effect of the imagination in this case reaches nearly half-way to the level of consciousness. If it were a little more than twice as strong it would be able by itself to produce an effect indistinguishable from a real sound.

Two copies of the same newspaper afford easily accessible materials for making this experiment, a few words having been altered here and there in the copy to be read from

I will conclude this portion of my remarks by suggesting that some of my audience should repeat these experiments on themselves. If they do so, I should be grateful if they would communicate to me their results.

#### PROTOCERAS, THE NEW ARTIODACTYLE

LAST year the American Museum of Natural History established a department of mammalian palæontology for the purpose of securing and exhibiting collections from all the tertiary horizons of the west. Dr J. L. Wortman, well known by his discoveries while associated with Prof Cope, was put at the head of the field work, and under his direction explorations have already been made in the Laramie or Upper Cretaceous, and in three of the great divisions of the tertiary, namely, the Wasatch, the Puerco, and the Lower Miocene or White River.

The discovery of the first example of *Palæonictis* found in America was mentioned in NATURE last year. From the Puerco are brought remains of about 400 individuals, adding many new facts to the discoveries of Prof Cope. From the Laramie are 400 of the small isolated teeth of the kind recently described by Prof Marsh. These are found by the writer to have a distinctly tertiary rather than mesozoic character, and while intermediate between the mesozoic and Puerco species, they decidedly resemble the latter *Mensiscoissus*, for example, about which there has been so much discussion, proves to be a plagiaulacid,

FIG. 1.—Side view of skull

and also an ancestor of *Polymastodon*, which is thus shown to be a huge *Plagiaulax*, in which the fourth cutting premolar is reduced.

By far the most perfect specimens have, however, been brought from the Lower Miocene, and here it appears that practically a new horizon has been developed, for the collection is full of fresh forms. Many of these are new species intermediate between the true White River or *Titanotherium* fauna, and the Middle Miocene, but others are new genera, and represent distinct unrelated forms.

In this Lower Miocene collection are included portions of six skulls and the fore and hind feet of an Artiodactyle, of about the size of a sheep. The most complete skull is here figured exactly as found, and is seen at once to depart from all known Artiodactyles in many important characters. There are no less than four protuberances upon each side of the skull. Hindmost are two processes upon the parietals, which are placed upon the superciliary ridges as they diverge from the sagittal crest. These processes are close together and oval in section, reminding us of the posterior pair of horns in *Uintatherium* rather than of the conical or rounded horns found in the giraffes and some other Artiodactyles. Their position upon the parietal bones is also peculiar. The superciliary ridges extend outwards into two widely projecting plates of bone, which curve upwards above the orbits; these plates are

upon the frontals, and the frontals also bear a pair of small conical processes just behind their junction with the nasals. But even more exceptional than these parietal and frontal processes are the great vertical plates rising from the maxillaries, slightly recurved, and reaching the full height of the parietal protuberances. Seen from above, these plates are found to be not in contact, but to enclose a long deep cleft, representing the anterior narial opening. This is bridged over posteriorly by the nasals, which, as shown in the second figure, are extremely abbreviated. Correlated with the development of these processes are a number of strong ridges, which form supporting buttresses for the horns. These extend, as above described, from the sagittal crest outwards, also from the anterior margin of the orbit forwards. This lateral maxillary ridge, as it may be called, terminates in a process just above the infraorbital foramen, and this process, although small, seems to illustrate the remarkable tendency of this little skull to develop osseous projections at every avail-

FIG. 2.—Top view of skull

able point. The character of these projections is different from that found elsewhere among the Artiodactyla, they are not horn-cores, neither are they similar to the processes upon the parietals of the giraffe. The development of these multiple bony protuberances suggests the skulls of *Sivatherium*, *Tetraceros*, and other eastern ruminants, but the proportions of the skull are wholly different. The olfactory chamber, which is usually so expanded in the Artiodactyla, is here extremely reduced, the nasals barely reach beyond the middle line of the skull.

Up to this point the study of the skull appeared to present an entirely new form, but later the other skulls were removed from the matrix, and among them one was found with small canine teeth, entirely lacking all the processes upon the frontals, and giving indications that those upon the maxillaries were either absent or comparatively small. The parietals were unfortunately missing, but the idea at once suggested itself that this might be a female skull. Two years ago Prof.

Marsh described a small Artiodactyle with a pair of small conical horn-cores upon the parietal bones, which he named *Protoceras celer*, expressing the opinion that it represented a new family. Upon the supposition that this type might also be a female of the same species to which the heavily-horned type belonged, the second skull was taken to the Yale Museum, and carefully compared point by point. It proved to be identical in every respect. In this way the discovery was made that in *Protoceras*, as in so many other Artiodactyles, the male and female skulls differed widely from each other in their cranial armature. The male was as described above, the female exhibits merely a pair of very small conical processes upon the parietals, with perfectly smooth frontals, and maxillaries either of the normal type or with smaller protuberances than in the male.

The dentition at first suggests relationship to *Tragulus* and *Hyomyschus*. The premaxillaries are edentulous as in the ruminants, but in the lower jaw there are four small teeth shaped like incisors, the outermost of which represents the canine. The upper canines are large,

FIG. 3.—Front view of Skull

pointed, and recurved. The molar teeth are of the short-crowned, or brachyodont type, with a distinctly crescentic pattern.

The structure of the feet also suggests the Tragulines, in the fact that the fore-foot has four well developed toes, while the hind-foot has two toes with the lateral pair very much reduced. As in the *Tragulidae*, the fore foot and probably the fore limb was very much shorter than the hind foot and limb. The hind foot, moreover, shows a tendency to co-ossification both in the metatarsals and in the union of the navicular and cuneiform with the cuboid. In many details, however, the feet present marked differences from the older and more recent Tragulines. The oldest of the Tragulines, moreover, is *Leptomeryx*, a contemporary of *Protoceras*, which has an entirely different skull and foot structure.

Taking all these facts together, we are led to support Prof. Marsh's conjecture, based upon the comparatively hornless female skull, that this Artiodactyle represents a new family, the *Protocerasidae*. We know absolutely nothing either of the ancestors or successors of this type, and this is another illustration of the fact which is constantly being impressed upon us, that our fossil-bearing strata still contain a great number of forms which are at present wholly unknown and unsuspected.

HENRY F. OSBORN.

#### HENRY F. BLANFORD, F.R.S.

MR. H. F. BLANFORD, whose death was noticed in last week's *NATURE*, was born in Bouverie Street, Whitefriars, in the City of London, in 1834. He was one of the students who entered the Royal School of Mines

at its commencement in 1851, and after distinguishing himself by taking the first Duke of Cornwall's Scholarship, he studied for a year at Freiberg in Saxony. In 1855 he and his brother, Mr W. T. Blanford, received appointments on the Geological Survey of India, and they landed in Calcutta at the end of September in that year. Mr H. F. Blanford remained on the Geological Survey till 1862, when he resigned, his health having suffered from the exposure incidental to geological surveying in India. His most important work whilst engaged on the Survey was the examination of the cretaceous beds of the neighbourhood of Trichinopoly, his classification of which, founded to a considerable extent on palæontological data, has been thoroughly confirmed by Dr F. Stoliczka's well known description of the fauna. Mr Blanford had previously, during his first season's work in India, by separating the Talchir strata, with their remarkable boulder bed, from the true coal-bearing, or Damuda rocks, taken the first step in what for so long was one of the most difficult tasks set before the Indian Geological Survey—the stratigraphical arrangement of the complex of beds subsequently known as the Gondwana system.

On leaving the Geological Survey he was offered a post in the Bengal Educational Department, and from 1862 to 1874 he was one of the professors of the Presidency College, Calcutta. Soon after 1862 he began to take a keen interest in meteorological questions, and after being for some time a member of a meteorological committee nominated by the government, he was, in April 1867, appointed Meteorological Reporter to the Government of Bengal, and placed in charge of an office established with a twofold purpose, to give storm warnings for the protection of shipping and to collect and record systematic meteorological observations throughout the Bengal presidency. Within a short time one most important result was obtained, the meteorological conditions under which cyclones originated in the Bay of Bengal were definitely ascertained, and it became practicable to say when a storm was a probable event, and in what part of the Bay it might be expected, and when a cyclone was impossible, although high winds might prevail. Meantime the various observatories of the country were being brought into order, and the observations rendered systematic.

In 1874 the Government of India became convinced of the necessity for placing all the meteorological observatories in India in communication with a central office, and Mr Blanford was finally transferred from the educational staff of Bengal and made chief of the new meteorological department, with the official designation of Meteorological Reporter to the Government of India. The new post involved much travelling to visit out-stations, in order to ensure the exact comparison of barometers and other instruments. The organisation of the new department, however, progressed rapidly, and in a few years a series of papers from Mr. Blanford's pen on rainfall, wind directions, and other meteorological phenomena gave evidence to all interested in the science that valuable additions to it were being made by the Indian observations. The peculiar geographical conditions of India render its meteorology unusually simple, and of great scientific and practical importance. An admirable illustration, both of the peculiarity of Indian meteorology and of the practical results yielded by accurate observations, is afforded by the fact that no sooner was the whole system in working order, than it was found practicable some time before the commencement of the monsoon season, and of the rainfall, upon which in many provinces plenty or scarcity of food depends, to prepare a forecast of the approaching season, and to warn the Government of a possible deficiency of rain in particular parts of the country. The forecasts prepared have been found remarkably accurate.

Mr. Blanford retired from the Indian Service in 1888,

and has since resided at Folkestone. Of late his health has gradually given way, and he died on January 23, at the age of fifty-eight. He was elected a Fellow of the Royal Society in 1880, and was an honorary member of several foreign meteorological societies. He was President of the Asiatic Society of Bengal in 1884-85.

That he was a man of considerable intellectual power is shown by the somewhat unusual range of scientific questions on which he has left works and papers. Besides his geological and meteorological reports, he wrote for the Indian Geological Survey descriptions of the *Nautlidae* and *Belemnitidae* of the South Indian cretaceous rocks, and he assisted the late Mr J. W. Salter in describing the Palaeontology of Nitt. He was also author of several papers on recent mollusca, and amongst his works are two treatises, one on the "Physical Geography of India," largely used as a text-book in Indian schools, and the other "An Elementary Geography of India, Burma, and Ceylon," published as one of Macmillan's Geographical Series.

### NOTES

WE learn from Sydney that steady progress is being made with the Macleay Memorial Volume, and that it will probably be ready for issue about the end of March.

AN announcement comes from Chicago that Mr Eadweard Muybridge, who, it will be remembered, visited this country some time since on behalf of the University of Pennsylvania, will give at intervals, from May to October, in the "Zoopraxographical Hall of the Exposition," a series of lectures on the science of animal locomotion, especially in its relation to design in art.

ON Thursday next, February 9, Prof Patrick Geddes will begin, at the Royal Institution, a course of four lectures on the factors of organic evolution, and on Saturday week, February 18, Lord Rayleigh will begin a course of six lectures on sound and vibration.

A TRANSLATION of Prof Weismann's new work on "The Germ-plasm," recently noticed in NATURE, will appear in the "Contemporary Science Series" in the course of a few weeks.

LAST week a deputation, representing the New Decimal Association, the Chambers of Commerce and Trades Unions, as well as various scientific institutions, waited upon Sir William Harcourt, Chancellor of the Exchequer, to urge the Government to adopt the decimal and metrical system of weights, measures, and coinage, or to appoint a committee of inquiry into the subject. Mr S. Montagu, M.P., as president of the New Decimal Association, having introduced the deputation, said that forty years ago there was great apathy upon the subject, but since then there had been inquiries by Select Committees and Royal Commissions into the question of the decimal currency, and though the reports of those bodies were satisfactory, no action had followed. The system had been adopted in Germany, Austria-Hungary, and Scandinavia; and in England there was now a good popular demand, such as Mr. Goschen said six years ago he was waiting for. Men of science like Lord Kelvin, Sir Henry Roscoe, and Sir John Lubbock, and educationists like Sir Philip Magnus and Dr. Gladstone desired the reform in order to economise brain-power; representatives of commerce desired it to assist them in their competition with rival nations; and the working classes were awake to the fact that years of labour were wasted by their children being compelled to learn that which could be rendered unnecessary. Several members of the deputation, including Sir Philip Magnus,

having spoken, Sir William Harcourt replied. He said that every one who reflected on the question must see the great advantages which attach to the decimal system. But the practical difficulties in the way of the proposed change seemed to him for the present to be insurmountable. A decimal system was introduced into Europe by the French Revolution. That was a time when the whole of society was cast into the melting pot, and they changed, not only their notation, not only their metrical system, but the names of the months and the days of the week. The change in Germany took place, not in quiet times, but as a result of the unification of Germany. He believed that even in the United States of America the change was made consequent upon the establishment of the Federal system. He did not think that the habits of the people could be altered in quiet times. This applied very much to the measures as well as to the coinage. Sir William was ready as an individual to play his part in forwarding the progress of the decimal system and the metrical system, but the Government could do nothing in the matter. The people would have to be prepared for so great a change.

IT is worth noting that instruction in the principles of the decimal and metric systems is daily given in public elementary schools, and that this labour—as Mr J. H. Voxall, secretary of the National Union of Teachers, has pointed out in a letter to the *Times*—is imposed upon the children without hope of practical good to the community. Mr Voxall contends that if an Act of Parliament were to fix a date of five or ten years hence at which the decimal system should come into legal operation, the work of the schools and the precaution of the mercantile classes would by that time sufficiently prepare the way.

A DESTRUCTIVE earthquake occurred on Tuesday morning at the town of Zante. Several houses were totally destroyed, many more were partially wrecked, and there is hardly a building in the town which has not sustained damage in one form or another. The roof of the prison collapsed during the earthquake, and the guards had to be doubled to prevent the escape of the prisoners. The hospital was also so seriously damaged that it was deemed expedient to remove the patients. The shocks, which were general, were renewed again and again, and the whole population was thrown into a state of panic.

DURING the past week the temperature over these islands has been fairly high, the daily maxima often exceeding 50°, notwithstanding a temporary fall, amounting from 12° to 14° in Scotland and the midland counties of England, on Friday, accompanied by much fog in the south and east of England, while the air has been decidedly humid, the readings of the dry and wet bulb thermometers frequently showing little or no difference. These conditions have been due to deep depressions arriving from the Atlantic and passing in close proximity to our western and northern coasts. In those parts gales have been of almost daily occurrence, and on Sunday they extended as far as the English Channel. Rain has been frequent, but generally the fall has not been heavy, and the sky has generally been overcast and dull, although on Saturday the weather over the south of England was unusually bright and fine. The *Weekly Weather Report* of January 28 shows that the temperature exceeded the mean in all districts, the greatest excess being 4° in Scotland. Bright sunshine also exceeded the mean in some parts of Scotland and in the eastern portion of England, but in other parts of these islands there was a deficiency.

A MAP showing lines of equal magnetic declination for January 1, 1893, in England and Wales, has been very carefully prepared by Mr. W. Ellis, and published as a supplement to

the *Colliery Guardian* of January 6, 1893. The explanatory text states that, as before, the work depends on the magnetic surveys of Profs Rucker and Thorpe. Mr Ellis gives a table showing the relation between the diurnal variation of magnetic declination and sun-spots, as determined from the magnetic observations made at the Royal Observatory, Greenwich. The general mean at epochs of minima of sun-spots is 7.4 minutes, and at epochs of maxima 11.4 minutes of arc, and other magnetic elements show a similar relation. The period between successive epochs of maxima or of minima of sun-spots is well known to be on the average about 11 years, and the author points out the curious fact that the interval between the minimum and maximum is on the average  $4\frac{1}{2}$  years, whilst from maximum to minimum it is 7 years. The relation existing between sun spot maxima and minima and the diurnal magnetic variation has led many meteorologists to seek for some similar connection with meteorological phenomena, but Mr Ellis states that no such relation has yet been conclusively established.

THE report of the administration of the Meteorological Department of the Government of India in 1891-92 shows continued activity and efficiency in all departments of the work, and bears testimony to the interest taken both by the public and by the *employés*. The number of observatories maintained by the Government at the end of the year was 165. As regards the actinometric work, an unusual amount has been done, owing to the favourable state of the weather, and the results have been forwarded to the Solar Physics Committee in London. The rainfall data are published month by month, and a large number of unsatisfactory rain gauges has been replaced by new ones. A larger amount of work under the head of marine meteorology has been done than in any previous year, several clerks are continually employed in collecting data from ships entering the various ports, and these observations have been utilised in preparing daily weather charts of the whole Indian area for a portion of the year. The systems of storm and flood warnings have been continued as in previous years, and observations have been taken in certain forests, in order to throw light on the influence of forest growth in modifying the distribution and amount of rainfall, a report upon this subject will shortly be prepared. Among the other papers being prepared for publication we note one on the relation between sun-spots and weather as shown by meteorological observations taken on board ships in the Bay of Bengal during the years 1855 to 1878.

At the meeting of the Royal Botanic Society of London on Saturday a plant of the Sisal hemp (*Agave rigida*) was shown from the Society's gardens. This plant is now extensively grown in the Bahamas and Central America for its fibre. The secretary said that until lately, with the exception of two or three fibre plants, as hemp and cotton, commerce depended upon wild plants for its supplies, but so great was the demand now for fibres for papermaking and other uses that it had been found necessary to grow them specially.

THE Sloyd Association of Great Britain met on Saturday to receive the annual report, to elect officers, and to appoint an examining body. It was agreed that "Sloyd" should be substituted for "Sloyd" in the name of the Association. The system of handiwork which the society is seeking to introduce into schools has already been pretty extensively adopted in this country, especially in the north of England. Mr Harris stated at the meeting that it was being received with approval in many different parts of the world. He had received communications from Napier, New Zealand, and Lahore, India, as to its adoption in these places.

AN American writer who was present at the Galileo Festival in Padua gives a very interesting account of it in the *New York*

*Nation*. He refers to the speeches delivered in Italian by Sir Joseph Fayrer and Prof George Darwin, to which we have already alluded. "They were," he says, "much appreciated by the audience. 'Parla bene!' 'Pronunzia bene!' one heard murmured in tones not devoid of surprise." The greatest orator of the occasion, according to this writer, was Prof Schmurlo of Dorpat, in Russia. "The type of the lonely and ungainly scholar in appearance, he nevertheless spoke a few phrases so ultra-Italian in the ingenious gracefulness of their turn, that the audience went fairly wild with delight."

THE latest instalment of the Transactions of the Institution of Engineers and Shipbuilders in Scotland contains an interesting paper, by Mr E. G. Carey, on the bridges of the Manchester Ship Canal. The paper is fully illustrated. The author notes that practically the whole of the bridge-work for this canal has been constructed in Glasgow from Scotch steel.

THE Smithsonian Institution has issued as one of its bulletins a full and very useful bibliography of the published writings of George Newbold Lawrence, the well-known ornithologist. The work has been done by Mr L. S. Foster, who gives also a short sketch of Mr Lawrence's career. Mr Lawrence's collection of bird skins is of great scientific value. It includes about 8000 specimens, and contains some three hundred types of new species of birds. The collection was deposited in the American Museum of Natural History, New York City, in May 1887. Mr Foster says that the beneficial influence of the labours of Mr Lawrence, with pen and pencil, on the progress of American ornithology, has been great and undisputed. It is particularly among the avifauna of the West Indies, Mexico, Central and South America, that his most strenuous efforts have been exerted.

IF we may trust a statement made on the authority of the Tokyo News Agency, it is not surprising that Japan is unwilling to be deprived of the privilege of fishing on the Korean coast. The number of Japanese boats engaged in the fishery is said to be no less than upwards of four thousand four hundred, of which about eighteen hundred have licenses. Their annual take averages from a million and a half of *yen* to two million value, and it is estimated that with more diligence and improved methods they might easily bring this figure to three or four millions.

IT is rather surprising that tobacco has been so little cultivated in Australia. The *Agricultural Gazette* of New South Wales, we are glad to see, has taken up the matter, and in its November number devotes to it a comparatively long and interesting paper. The writer of the article thinks that the climate of New South Wales is admirably suited to the growth of tobacco, and hopes that a sufficient quantity of it may hereafter be produced not only to satisfy local demands, but to open up a large and lucrative export trade.

ONE of the curious survivals of ancient prejudices in India is the intense dislike with which many high caste Hindus regard sea voyages. It is even disputed whether a Brahmin who takes a sea-voyage does not lose caste. The Maharaja of Mysore has not only emancipated himself from this strange notion, but is doing his best to overcome it in others. He lately made a voyage to Calcutta, and took with him a number of orthodox Brahmins, as well as Brahmin officials of state.

MR WALTER HOUGH, of Washington, notes in *Science* that among the collections from Mexico, Central and South America, exhibited in the Columbian Historical Exhibition at Madrid, he observed a number of oblong polished blocks of hard stone of unknown use, averaging  $3\frac{1}{2}$  inches in length,  $2\frac{1}{2}$  inches in width, and  $1\frac{1}{2}$  inches in thickness. The broad sur-

Faces of these stones are plane, bearing a number of grooves parallel to the length, forming ridges like those seen on Polynesian tapa mallets. The implements resemble closely, he thinks, those used by many different peoples in beating out fibrous bark for clothing, paper, &c. Mr. Hough suggests that they may have been used for purposes of this kind in prehistoric times, and that they may give some insight into the manufacture of the paper on which the Mexican codices are painted.

MUD GORGE, on the Hurnai route to Quetta, has been giving much trouble to the engineers engaged in the construction of the new railway. Landslips are frequent, and an unusually bad one has occurred within the last few weeks. On this occasion the hill, according to the *Pioneer Mail*, slipped in such a way "as to lift the rails bodily up and turn them over, sleepers uppermost." The mountain is said to be a great porous mass of clayey soil with large boulders imbedded therein, and it sucks in moisture like a sponge. After heavy rain it begins to move downwards, and even in dry weather disintegration goes on with disastrous results to the railway. New fissures are reported to have appeared hundreds of yards up the slopes above the line, and each of these indicates that thousands of tons of earth and boulders will sooner or later find a lower level. A committee of experts has been appointed by the Indian Government to examine the mountain thoroughly, and the *Pioneer Mail* truly says that "if they succeed in devising a means to conquer it they will achieve a notable feat in engineering."

Dr. Low, President of Columbia College, New York, has been stating in the *American Educational Review* his impressions as to the condition and tendencies of the higher education in the United States. One of the points on which he strongly insists is that a general college training should be considered necessary before students begin their University education in theology, law, and medicine. "The prophetic eye," he says, "can even now discern the day when a college education will be a condition precedent for entrance into the professional schools of the American university. This will not mean that only college-trained men will make good practitioners in law or medicine, for example, nor that only college trained men are entitled to a professional education. It will rather mean, I think, that the university will then have fully realised its own obligation to the country to send forth into professional life, in all parts of the land, men of a thorough and wide equipment."

ARCHÆOLOGISTS have observed that in Greek statues the male eye is strongly arched, while the female eye has rather a flattened surface; and referring to accounts by the older anatomists who have affirmed such a difference to exist, they have seen in this a fresh proof of the exact observation of nature by the ancient Greeks. The rule is not without exceptions, for the cornea in the Zeus of Otricoli has quite a flat form. Herr Greef recently set himself (*Archiv für Anat.*) to inquire whether such a sexual difference actually exists, and from individual measurement of the radius of the cornea in the horizontal meridian, he gets an average of 7.83 mm for men, and 7.82 mm for women (Donders gives 7.858 and 7.799), so the difference is so small as to be imperceptible to the naked eye. Measurement of other dimensions gave but minute differences also. The author concludes that the Greeks (from artistic motives) did not in this case follow nature.

THE difference between the aspect of the sky at full moon and the clear and deep azure observed on a moonless night is explained by M. Clémence Royer in his "*Recherches d'Optique Physique et Physique*" on the basis of some observations made by M. Piltchikoff. In studying the polarising action of the moon on the atmosphere, the latter found that the propo-

tion of polarised light in the nocturnal sky diminishes continuously from the time of the full moon up to that of the new moon, when it becomes zero, subsequently to increase again until the time of full moon. There appears to be a struggle between the polarised light of the moon and the so-called natural light of the stars, and the proportion of polarised light sometimes reaches 62 per cent. The diffusing power of the atmosphere necessarily varies with the relative proportions of natural and of polarised light, since the latter is not capable of reflection in all directions. Hence we see why very serene but moonless nights may yet be relatively very clear, and the sky of a beautiful sombre blue, whereas the white light of the moon, reflected, diffused, and polarised, tends to give the sky a tint of a paler and somewhat greyish blue.

At the last annual meeting of the American Association of Official Agricultural Chemists, the *Proceedings* of which have just been issued, Mr. N. T. Lupton referred in his presidential address to the immense phosphate beds in the south-western part of Florida. Last winter a visit was paid to some of the localities where deposits are found, and samples were collected for analysis. They were of two varieties, which may be called hard and soft. The hard variety consists of boulders of moderately hard rock, some of immense size, cemented together with white clay. A white and friable mass resembling kaolin is occasionally found. This is probably produced by the natural disintegration of the hard rock by rolling, attrition, or concussion. The deposits vary in thickness. A depth of 20 or 30 feet is not uncommon, and even a thickness of 50 feet has been found. Assume, especially foreign, manufacturers object to buying phosphates which contain over 3 per cent of oxides of iron and aluminium, large quantities of these materials have accumulated at the mines. A few manufacturers, aware of the agricultural value of South Carolina phosphate, have established mills in Florida for pulverising these soft aluminous deposits, which are sold to farmers for use without conversion into soluble phosphates. Experiments are now in progress on the Alabama Experiment Station, under control of the chemist, to determine the chemical composition and agricultural value of these soft phosphates when used alone with cotton seed and with cotton seed meal. If decomposing organic matter, as is believed, renders insoluble phosphates available as plant food to any considerable extent, Mr. Lupton thinks that the question of cheap phosphates will be solved, and that the American farmer will be enabled to purchase fertilisers at a much less cost than at present.

MESSRS W. H. ALLEN AND CO. have issued the thirty-seventh thousand of Dr. M. C. Cooke's "*Manual of Structural Botany*." The book is intended for the use of classes, schools, and private students.

THE February number of *Natural Science* includes, among other things, articles on some problems of the distribution of marine animals, by Otto Maas, on Pasteur's method of inoculation and its hypothetical explanation, by G. W. Bulman, the industries of the Maoris, by J. W. Davis, some recent researches on insect anatomy, by G. H. Carpenter, parasites on algae, by G. Murray; the underground waste of the land, by H. B. Woodward, Owen (concluded), by A. S. Woodward, and the restoration of extinct animals.

THE following are the arrangements for science lectures at the Royal Victoria Hall during February.—Feb. 7, Mr. J. Scott Keltie, on Africa and its people, Feb. 14, Mr. E. Wethered, on interesting objects under a microscope; Feb. 21, Mr. J. T. Leos, on breathing and burning, Feb. 28, Dr. H. Forster Morley, on chemistry of life.

THE additions to the Zoological Society's Gardens during the past week include seven Azara's Opossums (*Didelphys azarae*)

from the Argentine Republic, presented by Mr. Hill, a Rough Terrapin (*Clemmys punctularia*) from Guiana, presented by Mr. J. J. Quelch, C.M.Z.S.; an American Milk Snake (*Coluber eximius*) from Tennessee, presented by Miss Winifred M. Middleton, a Virginian Eagle Owl (*Bubo maximus*) from South America, deposited, two Mouflons (*Ovis musimon*, ♂ ♀) from Corsica, received in exchange.

### OUR ASTRONOMICAL COLUMN

THE NAUTICAL ALMANAC FOR 1896.—The new superintendent of the *Nautical Almanac* office has introduced a much-needed reform into the first almanac, that for 1896, issued under his direction. The state of the *British Nautical Almanac* has long been severely criticised as being far from the best possible for navigational purposes both in form and contents, and by no means satisfactory from the astronomical standpoint. A letter addressed by the Shipmasters' Society to Dr. Hind, the late Superintendent, in November 1891, pointed out the advantage to navigators which would be offered by a work published at a popular price, and without that astronomical information which is of no use to sailors. Many low priced almanacs are published, indistinctly printed, and having occasional errors in the figures, and an official trustworthy book was very desirable. In consequence of this representation the almanac is now published in two forms—as the complete almanac of former years, price 2s 6d., and as Part I. of the *Nautical Almanac*, specially suited for the use of sailors, price 1s.

The complete almanac has been revised and aided to, many of the recommendations of the *Nautical Almanac* Committee of the Royal Astronomical Society, which reported to the Admiralty in 1891, having been adopted. The small short period terms of nutation have been tabulated, and, corresponding to that, additional day numbers are added so as to enable computers to include those small terms in the star corrections. The catalogue of stars from which the moon culminators and stars occulted by the moon are obtained has been revised and enlarged, and the mean places of the stars of this catalogue, which are used during the year, are also included. The elements of the occultations are given in a revised form similar to that adopted in most of the other astronomical ephemerides, so that the circumstances of an occultation for any position on the earth's surface can be computed with facility. There has been a general revision of the constants used.

The small almanac has been arranged by Mr. Downing in conference with the Hydrographer. As the guiding principle in publishing this was the minimum of change in the parts of the almanac which were to be extracted and published separately, there is still much in the volume that is not needed by sailors, but the omission of which would have necessitated the setting up of fresh type and much extra work at the *Nautical Almanac* office. The monthly part is printed unaltered, and consequently contains the sun's and moon's latitude and longitude, which are not required by sailors. The noon ephemerides for the brighter planets, Venus, Mars, Jupiter, and Saturn, the catalogue of mean places of stars, as well as the apparent places of the nine stars used for lunar distances, the eclipse section and the tables for navigation are then given. There is no doubt that the issue of this smaller work will confer a real benefit on the shipping community, and that it will soon win its way to popularity.

In announcing these changes to the Royal Astronomical Society, Mr. Downing expressed the hope of being able, through the economy of time effected by international co-operation in some of the work of the office, to make considerable future additions to the almanac without increasing the burden of the British taxpayer. The duplicate work done at Berlin, London, Paris, and Washington involves much waste of energy which might be more usefully expended; and as a step towards this, Mr. Downing, last summer, arranged with Prof. Newcomb, of Washington, to co-operate in some of the work of their respective almanacs, and the Admiralty have consented to this. It is to be hoped, in the interests of astronomy and of navigation, that the scheme may be greatly extended.

ECLIPSE PHOTOGRAPHY.—The results obtained by M. de la Baume Pluvinel at Salut Isles in 1889 (as given in his lecture which appeared in *NATURE* last week), when he photographed the corona with photographic actions varying from 185 to 13, and found the photographic action of 30 the most satisfactory,

do not agree with those of the English expedition obtained at the same time and place. The photographic actions on the plates exposed with the 20-inch mirror of 45-inch focus, by the late Father Perry, varied from 19.75 to 790' as calculated by the formula given by M. de la Baume Pluvinel, and in every case increase of photographic action gave greater extension of the corona. Mr. Rooney's plates, with the 4-inch lens of 61 inches focus, had been subjected to photographic actions varying from 111 to 177.77, and agreed with Father Perry's in giving greater extension with every increase of photographic action. The English results certainly justify the conclusion that greater photographic action is necessary to photograph those faint extensions of the corona which have been seen, but have hitherto eluded attempts to photograph them.

Mr. Burnham's experiments, alluded to by M. Pluvinel, do not assist us in this question. A certain absolute amount of light is necessary to give any appreciable photographic effect on the plate, and this seems to be the chief difficulty in obtaining photographs of the external corona. In Mr. Burnham's experiments he had too much light and had to cut down the exposure in order to get faint contrasts, but there was never any question of not having sufficient light to obtain any photographic effect. Captain Abney finds (Phil. Trans. vol. clxxx. A, page 314) that an abrupt change of  $\frac{1}{2}$  per cent. in the intensity of light can be detected on a photograph, hence we may look upon a negative as a drawing built up of 200 different shades. Over exposure will of course prevent such faint contrasts as  $\frac{1}{2}$  per cent. being detected, and under exposure will enable fainter contrasts to be seen, so long as the limit of minimum exposure necessary to produce any photographic effect is passed, but the evidence from the English expedition renders it extremely probable that even with the largest photographic action used this limit was not actually reached with the faintest extensions of the corona.

COMET HOLMES.—Dr. F. Cohn, writing about this comet from the Observatory in Königsberg on January 17, finds (*Astronomische Nachrichten*, No. 3146), with a 6-inch heliometer and a magnification of 65 times, that the nucleus is exactly as a star of the 8th magnitude. The correction to the ephemeris given below is, as he has deduced,  $\Delta\alpha = -0.38$ ,  $\Delta\delta = -6''$ .

Dr. R. Schorr, of the Hamburg Observatory, puts the nucleus down on the same date as a 7.2 magnitude star with a small nebulousity about it of 5" diameter, but on the 18th he found the comet showed a much larger coma, a measurement giving 87". The stellar nucleus was also estimated as 7.5 magnitude of a diameter 2".

The ephemeris of this comet is from Prof. Schulhof's calculations (*Astronomische Nachrichten*, No. 3140) —

THE ANDROMEDAS.—Although Mr. Macair Boraston was unfortunate in having bad weather on the nights of November 13 and 14 last, thus obscuring the Leonides, yet the magnificent shower of the Andromedes that he describes in *Astronomy and Astrophysics* for January should have recompensed him some what for "the great elevation of the radiant point, combined with a cloudless tropical sky, the absence of moonlight and the unobstructed view of the complete hemisphere, afforded the *plus ultra* of astronomical requirement." Observing in

longitude  $72^{\circ}$  west and latitude  $17^{\circ}$  north, between 11h 48m and 5h 48m G.M.T., he deduced the radiant point from 70 short track meteors, and four coincident stationary ones, giving its position as R.A.  $28^{\circ}$ , decl.  $+36^{\circ}$ . Counts being taken at intervals for areas of  $60^{\circ}$ , about 18 meteors per minute were recorded, thus making a total number of 108 for the entire hemisphere in one minute, or 6480 per hour. As this fall went on continuously for six hours without any sign of the numbers diminishing, we have the number of meteors 38,880, which Mr. Boraston says must certainly be a minimum, as many faint and rapid ones must have escaped notice. A further observation at 9h 48m showed that the action was still being kept up, thus increasing this number to about 60,000. During this display it was remarked that the meteors appeared much brighter when distant from the radiant point than in its vicinity.

A NEW METHOD OF PHOTOGRAPHING THE CORONA.—M. H. Deslandres, in the *Comptes Rendus* of January 23, describes a method of photographing the solar corona without the aid of absorbing media. Sunlight is allowed to fall directly on a system of two identical prisms with parallel and inverted faces placed at a distance apart, such that only a portion of the diverging band from the first is intercepted by the second. After passing through the latter, the rays by recombination give rise to a well defined coloured image of the sun's disc. On displacing the prisms in a line perpendicular to the line joining them, the image assumes different colours, and on moving them along it, the range of colours intercepted is made to change. The prisms may be replaced by gratings. In a series of experiments carried off during the autumn, nine successive impressions of the sun's image were taken, ranging from the C line till far into the ultra violet. The object was to find the region where the light emitted by the corona showed the greatest photographic difference from that of the diffused sunlight in the atmosphere. As a matter of fact, a halo distinctly separated from the diffused sunlight showed itself on some of the negatives, especially in the ultra violet region, which very probably represented the corona. But to confirm this, simultaneous exposures at different, especially elevated, stations ought to be made, if possible during a total eclipse.
